A forensic odontologist compares dental radiographs/records of a suspected victim to any teeth or mandible recovered at a locus to confirm identity. Absolute identification requires the entire dentition, but unique variations of even a single tooth may help the process. If a tooth is lost during life, the tooth socket is, and the edges of it are not clearly discernible. By contrast, if teeth are lost after or around death (post- or perimortem), the socket walls remain identifiable and may be empty or dirt filled. There is no need to search further for teeth lost during life, although partial or total premortem tooth loss may suggest that a dental plate should be found. Teeth dislodged after death may be found by a systematic search of the soil between the skull and main decomposition site.

Trauma

Flies lay eggs in orifices, like the eyes and mouth, anus, and wounds. Consequently, initial maggot activity is concentrated in these areas. Large maggot masses away from natural orifices can indicate wounds on a partially decomposed body with no damage to underlying bones. The forensic anthropologist will assess the skeleton for trauma, including potentially defleshing a decomposed body, and localized maggot activity noted during recovery helps guide observations. Comparison to medical history of a suspected victim may assist in identification, while perimortem trauma may help determine cause and manner of death. Trauma that affects only soft tissues may not survive decomposition, with even violent deaths retaining no indication of attack on the skeleton.

To avoid inadvertent damage to bones during transportation from locus to the mortuary, separate long bones, the pelvis, skull, and mandible should be packaged separately, ensuring that the skull is especially well protected. Containers remain within the same body bag as the rest of the remains to ensure continuity of evidence.

Exhumations

Exhumation (disinterment) of a body legally buried in consecrated ground may be undertaken for an investigation of that individual's death initiated after burial; for an enquiry into another, potentially connected death that requires examination of that body; or if misidentification of the individual is alleged. Warrants require proof that examination of the body is important for the investigation. Separate permissions are needed for the exhumation and the removal of the headstone three days prior to the event. Further considerations are necessary if the plot is one having multiple occupancy. Information about the alleged deceased must be available, including name, age, weight, height, sex, and cause of death. A positive identification will be required, whether through DNA, fingerprints or from visual identification if possible. The grave must be photographed before, during, and after the exhumation. As with any body recovery, exhumations

require close adherence to health and safety, and personal protective clothing must be worn.

Soil is removed to just above the level of the coffin. Thereafter, screening helps avoid media attention and maintains the dignity of the deceased. Best practice is to excavate around the coffin, allowing side access. As the ground settles over time, coffins move and neighboring graves may merge into each other. Once the body is exposed to the air, it must be transported to the mortuary quickly since decomposition accelerates on exposure to air. Security is maintained at the grave site until reburial. A body transported from abroad may be embalmed, potentially affecting toxicological analysis of tissue, so chemicals used and methods employed should be reported. Common embalming chemicals include formaldehyde, methanol, monopropylene glycol, and mineral salts.

Soil from above and around the coffin, clothing, shroud, fluids, and sawdust from the coffin interior might be sampled, plus fragments of the coffin itself and any sealant used. An intact coffin should not be opened at the locus unless absolutely necessary due to the potential for disease transfer and evidence contamination.

Other Considerations at the Crime Scene

Legal Permissions

Valuable evidence can be excluded from court by paperwork errors or gaps in the chain of custody. The correct warrants, permissions, and protocols are needed before remains are recovered, searches made, or evidence seized.

Health and Safety

Personnel should wear latex or nitrile gloves (double gloved), liquid repellent disposable coveralls, protective shoe covers, particle mask/respirator, and goggles or face shield. Evidence seized should be packaged in the appropriate containers, properly labeled, and bags signed by witnesses. It is unacceptable to eat, drink, or smoke at crime scenes. Nondisposable equipment used should be decontaminated afterward with a 10% bleach solution. Regular comfort breaks should be taken outside the scene to prevent dehydration and overtiredness.

Additional Information

The area around the deposition site must be searched for tools, clothing, tire tracks, footprints, or other evidence. Consideration must be given to underground cables and pipes. If media, weather, or circumstances dictate, the deposition site should be tented, although this increases temperature and reduces natural light for excavation and botanical interpretations, so cases must be considered individually.

Crime Scene Analysis and Reconstruction

WJ Chisum, Elk Grove, CA, USA

Glossary

A Clue Is a physical item that, due to its environment and its relationship to the incident in question, yields information about that incident.

Bias Is a preference or an inclination, especially one that inhibits impartial judgment.

Critical thinking Is the intellectually disciplined process of actively and skillfully conceptualizing, applying, analyzing, synthesizing, and/or evaluating information gathered from, or generated by, observation, experience, reflection, reasoning, or communication, as a guide to belief and action. In its exemplary form, it is based on universal intellectual values that transcend subject matter divisions: clarity, accuracy, precision, consistency,

relevance, sound evidence, good reasons, depth, breadth, and fairness.

Emergency responses Concentrate on what society expects in a life-threatening situation. First, the scene must be secure from further threats by ensuring that the offender is no longer present; second, is the medical preservation of life; third, is the investigative phase which has as one goal the preservation of evidence.

Evidence dynamics Is any influence that adds, changes, relocates, obscures, contaminates, or obliterates physical evidence, regardless of intent.

Staging Is when evidence has been purposefully altered by the offender to mislead authorities and/or redirect the investigation.

Physical evidence cannot be wrong; it cannot be perjured; it cannot be wholly absent. Only in its interpretation can there be error. (Professor Paul L. Kirk)

Crime Analysis and Reconstruction

Crime analysis has been defined in several different ways depending upon the role the administrator, investigator, or forensic scientist has, that is defining it. This article will discuss crime analysis as a basis for crime reconstruction using the physical evidence.

Crime analysis starts within the confines of yellow barrier tape under the watchful eye of law enforcement officers and investigators and continues throughout the documentation and collection of the evidence. It is a broad inquiry that seeks to establish the record of the physical evidence produced during an event or a series of related events. It is ultimately the unified result of aggregated crime scene examination and processing efforts; forensic laboratory examinations and analyses; medicolegal examinations and analyses; and collateral victim-suspect history. Crime scene analysis is used to establish the facts; the forensic scientist then uses those facts to determine how the crime proceeded.

Crime scene analysis depends upon objective observations without premature interpretation that may be influenced by otherwise harmless bias. Bias is a natural component of human thought processes and takes many forms. To be able to recognize and minimize bias is a prerequisite for reconstruction. The reconstructionist that does not go to the crime scene is impaired by the biases of those selecting the evidence to be analyzed.

For the purpose of reconstruction, evidence is anything that supports or refutes anyone's theory about any of the phases that occur in the pre-commission, commission, and post-commission of a crime.

Phases of a Crime

Crimes have certain behavioral processes or phases in common, of course, not all of the phases will be present in every crime. The following are the phases that may occur:

Fantasy: The person thinks about the crime, whether it is getting money and what can be done with it or the rape or murder of a person. Thinking about these crimes is fantasizing. They may write about their thoughts, even on the Internet, or draw sketches giving information regarding their reasons for the crime, they are thinking about doing.

Planning: When the person decides to actually commit the crime they may discuss it with others in person, on the telephone, or on the Internet. They may even prepare a kit for committing the crime or purchase a gun. Not all crimes are planned in advance, sometimes they are spontaneous, occurring as the opportunity presents itself.

Approach: This may take different forms in the approach to a victim; anything from a sudden attack to a subtle con as used in the movie 'The Silence of the Lambs' to get the girl into the van.

Control: The perpetrator has control of the situation. This may be in the form of transportation, such as inside a vehicle, has tied the victim, has locked the doors, or in a non-violent crime, has gained entry without setting off an alarm.

Aggression: The perpetrator now starts the attack. This is the primary criminal act such as robbery, rape, assault, homicide, or other crime.

Response: The victim responds to the act of aggression. The victim may fight, breaking the control of the perpetrator, taking control of the situation themselves such as obtaining a weapon or by talking the perpetrator out of further acts, or attacking the perpetrator with violence. The victim may also panic, resulting in running away or assuming a fetal position.

Disposal/display: The perpetrator may continue aggressive acts on the victim resulting in 'overkill' or in necrophilia. They may try to cover up the crime by dismemberment and/or disposal. They may pose the victim to satisfy their fantasy or for further 'embarrassment' to the victim when they are found.

Staging: The perpetrator may rearrange the scene or plant something that shifts the blame away from him/her, to implicate someone else or to make a homicide appear to be a suicide or accidental death.

Flight: The perpetrator leaves the scene, perhaps taking a souvenir or trophy.

Alibi: The perpetrator devises a story to show that he could not be responsible.

Fantasy: The perpetrator fantasizes about what happened and then starts thinking about how to do it again (the serial criminal). They review the actions and think how they could improve on them and start the cycle over again.

Crime analysis should also include an evaluation of the victim. Why was this victim chosen? Why was this location chosen? These questions may or may not be answerable from the physical evidence at the scene. Some will require that the victim and witnesses be interviewed by the investigators. However, no statements should be accepted unless consistent with the physical evidence.

These phases should be kept in mind as the crime scene is analyzed. Later, when they have been noted, they should provide a basis for reconstruction and discovery of less important evidence or lead to other analyses. Are there items of evidence that contribute to one or more of these phases? Do not assume for instance that the blood pattern on the wall is cast off from a weapon produced in the aggression phase. The victim's response may have been to grab the wound, then move their hand rapidly casting off the accumulated blood. The crime scene analysis needs to describe the weapons, wounds, locations, the scene, and the background of the victim before bloodstains are interpreted. The analysis of the crime scene should give the investigators information that can be used in interviewing witnesses and potential suspects. They need to be aware of the scene characteristics, physical dimensions, initial phases of emergency response and ensure that the subjects being interviewed correlate their stories with those facts.

Evidence Dynamics

One must enter each scene with an open mind, have no assumptions regarding the types of evidence that one may encounter. Assumptions are made though one may not realize one is making it. For example, one receives a call to respond to a crime scene and one is given information about the case. If one has seen cases of this type before, one knows what to expect at the scene. One tends to work the scene as one had done in the past. One sees what one expects to see. This attitude can result in serious impediments to crime scene analysis and to the investigation. For instance, if one is being sent to a death scene, one should not be told that it is a suicide. It could be staged to appear to be a suicide but may really be a homicide.

As stated by Hans Gross 'We must forget the past and work each case based only on what we see.' This was a warning against one of the various forms of bias that is encountered.

One must realize, too, that the scene is not necessarily the same as it was immediately after the crime happened. The scene may have been changed by the perpetrator, victim, or the witnesses or by time and the environment. It has definitely been changed by the first two phases of emergency response. The first officers at the scene have the primary duty of protecting life: first their own, then the lives of others, and the duty to apprehend the perpetrator. The protection of evidence has low priority. Preservation of fingerprints on a closet door knob are not a concern, and should not be, when the officer opens the closet to see if the perpetrator may be hiding therein.

The second phase of emergency response is the life-saving efforts of medical technicians or others giving CPR or other life-saving measures. Evidence is frequently destroyed, altered, or created by these activities. Investigators, technicians, and forensic scientists who respond to crime scenes must be cognizant of these changes.

The first officer must be interviewed before the crime scene is entered. Find out what has been changed by the first responders. If the officers moved a weapon or lifted the body to search for one, the evidence will be altered. Giving CPR to a victim will cause blood patterns that can be confusing. Such actions can cause misinterpretation of the evidence in the crime scene analysis. Time will be wasted analyzing the bloodstain patterns caused by the actions of the EMTs transporting the victim. Interview someone who is familiar with the scene area to see what has been changed by the actions of the offender(s) and the victim(s).

The victim is a part of the scene. Movement of the body may change bloodstain patterns. The transportation of the body to the morgue in a body bag will change and destroy pattern and trace evidence. All these changes have to be anticipated. Some are predictable but others are not, such as insect or animal damage to the corpse.

The autopsy constitutes a secondary scene. The crime scene analyst will have a different background than the medical examiner (hopefully a board certified forensic pathologist) and, therefore, will look for different things. Teamwork and open communication by the analyst, investigative personnel, and the pathologist will result in maximum information from autopsy. In some jurisdictions, the doctor does not allow outsiders in the autopsy. Yet the doctors should have the scene described to them and need to communicate with the investigators in some manner as the autopsy is being conducted.

The Reconstructionist needs all the information possible in order to develop the who, what, where, when, how, and sometimes the why of the crime. The crime scene must be thoroughly documented. New technology based on the 'total station' and high-definition digital photo integration producing three-dimensional holograms of the crime scene are possible, but must be supplemented with sketches and photos on the computer. It has been said that 'Any reconstruction can only be as good as the information provided.' New instruments provide more detailed information but isolation of certain photos may be necessary to see relationships that build a reconstruction.

Role of Physical Evidence

There are several different classifications used by forensic scientists to classify the evidence. Some classify based on the types of analyses that will be undertaken such as trace, biology, chemistry, etc. Others by the types of crimes, homicide, assault, burglary, etc. The reconstructionist benefits from recognizing the role, the physical evidence plays in the reconstruction. The use of this classification has the analyst starting the reconstruction process when the evidence is first recognized.

Evidence may be transitory, relational, or functional.

- Transitory evidence is something that does not remain, it could be an odor, water which evaporates, ice, a burning cigarette, clothing position of the victim, temperature etc. If transitory evidence is not noted upon arrival at the scene, it will be lost.
- Relational evidence has a relationship to other items at the scene and/or a relationship to the crime. Essentially it is clue evidence. A pistol, bullet, casing, powder, and trajectory are related to each other.
- Functional evidence is how something works. It can be mechanical, chemical, electrical, electronic, or biological.

The evidence may be further subdivided into the role it plays in the crime:

- *Action* evidence establishes direction and velocity. It shows what the actors did or what was done to them.
- *Location* evidence establishes the positions of the actors or where some action took place.
- *Directional* evidence establishes the direction something was going or the direction it came from.
- *Sequencing* evidence establishes the order of occurrence of events.
- *Limiting* evidence establishes the crime scene.
- *Ownership* evidence establishes the owner of the items.
- *Implied* or derived evidence is the absence of something.
- *Temporal* evidence establishes the duration of an event, distance, and when a crime occurred.
- *Psychological* evidence is something at the crime scene that is added, removed, or arranged in a particular way to satisfy a need of the perpetrator.

The above classification scheme is part of the crime analysis. By listing the items of evidence and assigning them the roles that they play in the crime, new relationships and logical conclusions can emerge which will aid in the formation of a reconstruction.

Reconstruction – Historical Perspective

To reconstruct a crime, or any event, one must be able to see the effects and infer the cause. People observe the cause and then see the effects, but most do not do the reverse.

In solving a problem of this sort, the grand thing is to be able to reason backwards. That is a very useful accomplishment, and a very easy one, but people do not practice it much. In the every-day affairs of life it is more useful to reason forwards, and so the other comes to be neglected. There are fifty who can reason synthetically for one who can reason analytically. (Doyle, 1887)

Sherlock Holmes was the epitome of the ‘scientific detective.’ He conducted experiments and had collections of various materials so that he could identify not only what they were but, in many instances, where they came from. He also used scientific thinking to solve cases. Sherlock Holmes was fictional; Arthur Conan Doyle wrote the stories. He apparently based the methods on his mentor Dr. Joseph E. Bell.

Did Doyle come up with reconstruction on his own or was it part of the investigative processes at the time? The stories show how clues are used to ‘think backwards’ and reconstruct the incidents. ‘Even the forensic scientist himself owes his existence and attitudes a good deal more to Conan Doyle, and a good deal less to Newton and Darwin, than he is usually prepared to admit.’ (Kind, 1977)

Scientific reconstruction of crimes was practiced in the 1930s. Henry Rhodes stated that, ‘From one point of view it might be said that the technique of reconstruction is a modern development in the detection of crime.’ Its object was to decide how the crime was probably committed and the order of events. ‘Scientific instruments and expert diagnosis make possible increasingly precise technique of reconstruction. It is a necessary part of the study of any modern crime concerning which there is an element of doubt.’ (Rhodes, 1933)

While an element of doubt seems to be a questionable criteria for needing to reconstruct, forensic scientists seldom get to see those cases where there is no element of doubt. They do not get the case unless someone wants them to develop some information about it. ‘Information can only be received where there is doubt; and doubt implies the existence of alternatives – where choice, selection, and discrimination is called for.’

The ‘Wizard of Berkeley,’ Edward O. Heinrich was a practicing reconstructionist in the 1930s–40s. He stated that his method of criminal investigation was:

Crime analysis is an orderly procedure. It is precise and it follows always the same questions that I ask myself. Let’s consider what they are:

Precisely *what* happened?
Precisely *when* did it happen?
Precisely *where* did it happen?
Why did it happen?
Who did it?

The average investigator seem to give immediate attention to the *why* and *who* but he takes what happened for granted. We must analyze the method of the crime before we can analyze its purpose and look for the criminal.

I have always held that the criminal virtually labels every crime he commits. My procedure is to reconstruct the crime by visualizing the habits and actions of the criminal. I do this by using the debris that the criminal leaves behind and relocating it with respect to the criminal episode. So I make the natural sciences interpret what I have observed. (Bloch, 1958)

Heinrich did not teach classes on Forensic Science even though he was a Professor of Criminology at UC Berkeley. That role fell to Paul L. Kirk. Professor Kirk was also interested in the how, when, what, and where, more than he was in the why and who of crimes. He instilled a questioning attitude in his students that resulted in many of them becoming leaders in the forensic field.

Who Does Reconstruction

A well-documented scene is the primary requisite for a reconstruction. Any evidence not collected may result in an incomplete or, worse, an erroneous reconstruction. Therefore, any bias that influence the recording of the crime scene or the collection of the evidence will cause errors. Unfortunately, the Forensic Scientists who respond to crime scenes are diminishing. Evidence technicians, for the most part, do not have the same approach. Too many are told what to do and what to collect. There are also some who are very competent and do try to eliminate any bias from their crime scene work and reconstruct the events of a crime. However, they lack the science that allows them to interpret the crime laboratory findings. This too, is not a new situation, O'Hara and Osterburg described the laboratory analyses as 'a routine affair which may be entrusted to an ordinary technician,' and stressed 'the importance of field work for the working criminalist.' (O'Hara and Osterburg, 1949)

Detectives frequently do preliminary reconstructions. They then select evidence that supports their theory of the crime. Unfortunately, the physical evidence has not been analyzed and the detectives are basing their reconstructions on experience. 'the use of one's experience as a knowledge base for developing reconstruction hypotheses and theories, or for inferring the cause from an examination of the effects, is commonplace. It is consequently important to bear in mind that not all experience is equal, not all experience is sufficiently instructive, and not everyone learns from his or her experiences' (Chisum and Turvey, 2007). The purely 'experience-based reconstructionist' may give examples of his conclusions to demonstrate how he reconstructs but often will not be able to show the logic and science behind his methods. The absence of such 'long division' in his work is in effect an absence of science. In addition, if an arrest is made or a suspect is identified, then the detective concentrates on proving his theory and that this suspect is guilty.

If there is no forensic scientist looking at the case, attorney's will form a reconstruction to present their evidence to the jury or court. The DA has conviction of the crime as the primary goal. The reconstruction they make, will make the crime heinous and the defendant's role in it as significant as possible. The defense will take the opposite view and try to present a reconstruction that eliminates any possibility that the defendant is responsible for the crime. Attorney's have no scientific basis for their reconstructions, just that they support their side of the case. The reconstruction should not be left until the final moment (court) before it is presented.

Methods of Reconstruction

The reconstruction of a crime is to reconstruct several small things first. For example, in a shooting case: the bullet bearing the victim's DNA is compared to test bullets; the weapon is fired (with the same ammunition) at various distances to determine the muzzle to target distance from the gun powder residue; the angle through the body; the location of blood spatters and their nature; and the location of any casings

from the weapon are used to establish the position of the shooter relative to the victim. This is utilizing the scientific information in reconstruction of a shooting (a singular event or event segment not the entire crime). Each hypothesis is now tested against the stories told by the shooter, the victim, if alive, and any witnesses. It is also tested against any hypotheses the police or prosecutors may have. The individual laboratory tests that were done are used to strike down any hypothesis that has a conflict with the scientifically developed information. This is the primary use of reconstruction, *premise negation*.

The hypotheses that were proposed by the laboratory analyses are that the DNA match on the bullet shows that the bullet struck the victim; that the blood spatter pattern has significance; the powder patterns do give the distance; and the casings eject in a certain manner. These are the things that are tested in the experimental phase. The results are, provided they are done correctly, as scientifically valid as possible. There may be other evidence that will shed more light on what happened. However, one is not looking to establish a theory of reconstruction; one is eliminating the stories that are being told about the case. This is the primary use of reconstruction and builds a rapport with the investigator. One uses the physical evidence to develop what are called facts that are used to test the theories or stories about the incident.

One method is to take all the stories that have been presented. List them across the top of a table as 'theory 1,' 'theory 2,' ... Then list the physical evidence derived information in column 1. Mark the chart for each item of information with a 'C' for consistent, 'X' for excluded, 'I' for inconclusive. This works well when witnesses tell multiple versions of events or when there is a disagreement between investigators. It is a simple way of using reconstruction, if all the versions are excluded, refine the elements that are consistent to see if another theory can be developed. This is essentially the same as the 'Storyboard' concept that Rynearson uses in his 'play' analogy process.

Brian Parker stated that 'The goal of the crime lab is to prove the investigator wrong.' This philosophy may sound wrong to many, but it is the basis of tests. If one adopts this philosophy then one will be eliminating much of the bias that is inherent in almost all endeavors we undertake. But, one must extend that philosophy to all theories that one is presented with, even those of colleagues.

Bevel and Gardner have developed an event-sequencing methodology for reconstructing crimes. They define the overall crime as an incident, events are major aspect of the occurrence, and specific actions as event segments.

A crime scene analysis then is reverse engineered. We use evidence and data to define event segments. Since this reconstruction method attempts to define the crime or incident by establishing these events and event segments, we call the process Event Analysis. The steps taken to create a crime scene reconstruction using Event Analysis are:

- Collect data.
- Establish specific event segments (time snapshots).
- Establish which event segments are related to one another.
- Sequence those related segments, establishing a flow for that event.
- Consider all possible sequences, auditing the evidence when necessary to resolve contradictions.

- Based on the event segment sequence, establish final order of the events themselves.
- Flowchart the entire incident and validate the sequence.

One of the criticisms of this methodology was that it was quite similar to the Multi-Event-Sequencing methodology developed by Gustav Benner many years ago. The two have got together and shared information. This has resulted in Mr. Benner making suggestions as how his flowcharts and methods could be adapted for crime scene reconstruction. This produces a nice charted sequence of events. However, the sequence cannot be developed without information (not data—data is used to develop information). The relationships that exist between items is not always obvious nor are the ‘event segments.’

Event segments must also be studied with scientific methods. Each event segment is a hypothesis and will have alternatives. These alternatives must be eliminated so that the event segment becomes the most probable. Failure to follow the process with all inferences (hypotheses) will not result in a meaningful reconstruction.

There are several approaches to understanding relationships between items of evidence. Critical thinking is needed which means using imagination, logical, and scientific reasoning processes. It also entails ‘thinking outside the box,’ after all the incident one is reconstructing is something that occurred ‘outside the box’ whether one defines the ‘box’ as the law or the norms for society.

Faye Springer of Sacramento uses a 3 × 5 card for each item of evidence. She lists what is known about that item on the card. Then she spreads the cards and associates them as she sees things in common. This is essentially a manual technique of *mind-mapping* which also has proved to be a useful technique.

The author uses ‘The Brain®’ software. The Brain® gives one the ability to see relationships and to do Event Analysis on the computer. It helps to see data, develop information, and put it in a logical order. The full version (as opposed to the free version) allows photos, files, and Internet sites to be incorporated into the matrix. These methods can also use the classification scheme for evidence (directional, temporal, etc.) as given previously.

If there is a group, then *brainstorming* is a technique whereby several minds are working on the problem. This has proved to be a good technique when done properly. There are instructions on how to brainstorm on the Internet.

Joe Rynearson proposed that a crime scene is like a play.

The commission of a crime can be likened to a movie or a play. There are actors, the stage, backdrops, acts, and scenes, as well as dialog and actions revolving around a script which has a defined

plot. Each scene also includes ‘stage directions,’ which give additional information as to where actors should stand, move and how they should act. If we understand the stage (the crime scene), then we have a chance to learn what actions may coincide with them.

A crime scene reconstruction may portray specific actions and perhaps even place them in sequence; however, it is unlikely that a continuous ‘flow of actions’ (like the script of the play) can ever be achieved. Though some investigators would represent a crime reconstruction as a continuous portrayal of the entire ‘plot and script of the play,’ this is not possible. The very best that can actually be achieved is to develop the separate (and brief) ‘stage directions’ for each scene of the play and of *ALL* of the logical alternatives to connect them together.

To summarize, the forensic scientist studies the reports, photos, and diagrams. They use logical inferences to come up with hypotheses for all kinds of causes for the effects seen. They then eliminate hypotheses until they have eliminated all the alternatives but one. When they ‘have eliminated the impossible then whatever remains, however improbable, must be the truth.’ (Doyle, *The Sign of Four*, 1890)

Suspicious Deaths

J Horswell, Approved Forensics Sendirian Berhad, Selangor, Malaysia

© 2013 Elsevier Ltd. All rights reserved.

Cause of Death

To understand suspicious death, the crime scene investigator should understand the various causes of death and the manner in which death may occur. The cause of death refers to the disease or injury responsible for initiating the chain of events that result in death. Some examples of causes of death include cancer, heart disease, pulmonary embolism, gunshot wound(s), stab wound(s), and asphyxiation by strangulation or hanging. They may be acute or chronic. The cause of death should reflect the first event that sets into motion a number of sequential events, such as broken bones from a blunt injury leading to immobilization resulting in pulmonary embolism, in which, the blunt trauma is the original cause, whereas the pulmonary embolism is the final cause of death. One would expect the cause of death to read 'Cause of death = Pulmonary embolism due to blunt trauma injury to the skeletal system [here nominate the bones broken].'

Manner of Death

The manner of death relates to the circumstances in which the death occurred and is generally divided into five categories:

- 'Natural' death is due to a natural process or disease.
- 'Accidental' death is due to the unintentional or inadvertent actions of the deceased or another person.
- 'Suicidal' death is due to an intentional act or acts of the deceased who anticipates his/her resultant death.
- 'Homicidal' death is due to the direct action of another, which results in the death of a person.
- 'Undetermined or unknown' death is where the surrounding circumstances cannot be determined with reasonable certainty.

It is important for the crime scene investigator to be knowledgeable about the death scene and for the forensic pathologist to attend the scene; however, this is not always possible, particularly, in rural or remote communities.

A heavy burden is therefore placed on the crime scene investigator who must have the knowledge and skills to understand fully the various causes of death and the manner in which the decedent met death. This can only be achieved by visiting as many death scenes as possible. Scenes provide important information that may indicate cause of, and means of, death. The environment at the scene may help explain the condition of the body when it was discovered. If the deceased died while lying close to a heater, the body will decompose faster than usual. If the deceased collapsed onto an irregular or rough surface, this may explain minor injuries that are found on the body. Postmortem injuries should not be confused with antemortem injuries. Cause of death may be obvious, for example, a gunshot wound to the head; however, to determine

the manner of death, further information will be required, such as whether this was an accident, suicide, or homicide.

Death scenes should be treated as homicide scenes and dealt with as such until the contrary is proved. This can only be achieved through detailed examination and investigation.

There are now two distinct tasks ahead of the crime scene investigator. The first is the technical recording and retrieval of potential physical evidence from the scene. Just as important is the second, the reconstruction in the mind of the crime scene investigator of the events and circumstances surrounding the death. This article will discuss the technical issues first and the reconstruction issues second.

Death Scene

When violent or suspicious death is discovered, the death scene should be secured immediately so that no one will have an opportunity to change it. Indoor scenes may be easy to secure and protect. Outdoor scenes can be difficult. The more urban the scene, the more difficult it is to secure, as there will be a need for several scene guards and the setting up of cordons. The more remote the scene, the easier it is to secure. The weather and movement of predatory animals through the scene common approach paths, and the maintenance of a scene log to record visits to the scene, add a dimension to the processing of a crime scene and the condition in which the deceased may be found. Outdoor scenes may be cooler than indoor scenes, and the weather can have an impact as can the movement through the scene by animals. Any disturbances must be recorded.

The crime scene investigator should take photographs and video recording of the scene immediately before anything is moved. 'Stepping plates' may be used to secure a route to the body preserving any evidence that maybe under each plate for later recovery as each plate is removed. Notes and a sketch should be made at this time. The deceased's location relative to other objects and structures within the scene is very important. The actual position of the deceased is plotted: the head and crutch are good points on the body to use for plotting its position. Accurate measurements of the deceased relative to other potential physical evidence and the scene fixtures must be made to place items appropriately within the sketch made at the scene. Great care should also be taken to preserve any footwear marks or other significant evidence types around the body.

The deceased is the most valuable piece of potential evidence at any death scene. Hence, the systematic and thorough examination of the body should be undertaken at the scene. Blood, weather conditions, location, and poor lighting may mask faint injuries and trace evidence on the body; therefore, the crime scene investigator should document in writing, by sketch, and by photographic recording all information about the body that can be gathered at the scene. The remainder will

have to wait until the postmortem examination. The attendance of other experts at the scene may also be considered, for example, biologist, entomologist.

The environment in which the body was found will affect the rate of body cooling. The wind conditions, the temperature, and the presence of rain should be noted. The crime scene investigator will need to develop a general description of the deceased, including, where possible, the gender, race, age, height, and weight.

One of the first most important questions that will require an answer is, did death occur at this locus? The position in which the deceased was discovered is of particular importance, as it will provide an indication as to whether or not the body was moved before being discovered. The presence or absence of rigor mortis or stiffness of the body, whether it is absent, minimal, moderate, advanced, or complete, will help the crime scene investigator and the pathologist determine if the person had died at that locus, in the position, as found. The crime scene investigator should inspect the body for postmortem lividity, hypostasis, or livor mortis. A pink-purple discoloration is usually present at the lowest point of the body. This is due to the settling of the blood by gravitation. Its location and state of fixation should be noted and photographed. For example, unfixed livor mortis blanches white when moderate pressure is applied as opposed to fixed livor mortis, which remains the same color when pressure is applied. If livor mortis is noted on the deceased in areas not consistent with it, forming in the lowest parts of the body, the crime scene investigator should consider the possibility that the deceased was moved after death.

The blood flow patterns should match the position of the body. If the scene is one of apparent violence, the blood flow or splash patterns can indicate the use of a weapon and in some cases indicate the type of weapon.

Is the trace evidence at the scene consistent with the death having occurred at this locus? Does the body contain any trace evidence that is unusual for this locus, for example, mud on soles of shoes and/or grass and/or seed material found on the clothing when the body has been located inside a house? Is the death one that can be attributed to natural causes? Is there any external sign of violence? Is there anything about the scene that arouses the crime scene investigator's suspicions?

The crime scene investigator should consider several hypotheses and then set out to prove or disprove each one. The physical evidence present, together with the known facts, should be sufficient to enable the crime scene investigator to develop a reasonable hypothesis as to what has happened at the scene; however, this is not always possible. Suspicions may not be roused until the postmortem examination reveals something that was not apparent at the scene. The pathologist may, however, provide the investigating officer with a definitive indication as to the cause of death, giving investigators lead(s) to start their lines of inquiry.

Before the deceased is moved from the scene, the crime scene investigator should begin the examination of the body systematically, locating potential physical evidence that may be lost during transportation, noting and photographing trauma before removing any identified potential physical evidence, and packaging each item separately. The taking of body swabs and tape lifts may be considered at this stage.

The deceased's hands, feet, and head should be bagged using paper bags, as the use of plastic and any subsequent refrigeration will cause plastic bags to sweat. The bags should be large enough to be taped securely around the wrist, ankle, or neck and should allow 'ballooning' over the area to be protected. The body should then be placed into a new, clean body bag. If face down, it should not be turned over during this process so as to avoid 'flooding' wounds and thus damaging evidence. A thorough examination of the area that was previously obscured by the body may now be conducted. The deceased should then be transported to the mortuary for a full postmortem examination. This is then the realm of the forensic pathologist.

Postmortem Examination

The postmortem examination is normally carried out by an experienced forensic pathologist. The crime scene investigator should be present, as should the investigating officer or his/her delegate.

The deceased should be taken from the body bag and all packaging items should be retained for a subsequent search for trace evidence in the forensic science laboratory. The crime scene investigator should then record photographically the clothing and the condition of the body and take a facial photograph for use in identification processes. The forensic pathologist should be taking notes and making diagrams of the overall body and any item of evidence or wound(s) or external markings located.

The clothing should be inspected and any obvious trace evidence removed and then the item should be packaged. Each item of clothing should be removed and packaged separately. It is at this time that wallets and property should be removed from the deceased's pockets and the contents noted and the items packaged separately. It may well be that these items are of no forensic value, as such, and thus may be released into the custody of the investigating officer. All items of clothing should remain in the custody of the crime scene investigator.

An external examination should be conducted next. Questions may already exist that need answers. Are there any marks of violence, such as stab or gunshot wounds, ligature or restraint marks, injection sites, or blunt injury wounds? Are these injuries incompatible with life, or could the person have lived and moved for a time after sustaining the injuries, thus explaining some of the evidence located at the scene? Could the deceased have inflicted these injuries? Were there other persons involved? Do the injuries appear to have been made ante mortem, at the time of death, or postmortem? Bleeding into the tissues (bruising) usually means that the deceased was alive at the time of the injury. Are there any injuries that could be regarded as 'defense' wounds? These would indicate that the deceased was alive, alert, and aware that she/he was being assaulted and aware of the life-threatening nature of the assault.

The crime scene investigator should search the body using oblique lighting. This is a method highlighting minute particulate matter and/or bruising that, under normal lighting, is difficult to see.

At this stage of proceedings, the forensic pathologist should take fingernail scrapings, with each digit's scrapings being placed into a separate and labeled container. The next sample to be obtained is the hair samples, which should be recovered from a site of interest and individually packaged in labeled containers. These samples should remain in the custody of the crime scene investigator. A complete series of radiographs should then be taken. These may reveal broken bones, projectiles, foreign bodies, prostheses that have been inserted into the person while alive, and major deformities.

Identification may be an issue. Identification is important in both civil and criminal law. It provides proof of the person's death. It allows for

- notification of next of kin,
- completion of the death certificate,
- eventual disposition of the remains,
- settlement of the deceased's estate, and
- identification in criminal proceedings.

Visual identification, although the most frequently used method of identification, is subjective and can be unreliable, as many people bear a resemblance to each other. The person making the identification can also be so shocked by seeing the deceased that she/he can make a false identification owing to being in a state of denial. Forensic identification techniques should also be employed. These include the following:

- A general description of the deceased: color of hair and eyes, height, the presence of scars (accidents or operations), marks, and tattoos.
- A general description of the clothing: type, color, and fabric of each item.
- A forensic odontologist should be requested to X-ray, chart, and make any casts necessary of the deceased's teeth prior to the postmortem examination begins. These may be later used for comparison purposes.
- DNA samples (see below).
- Contents of the deceased's wallet.
- A medical records search for any major operation, broken bones, or the addition of any prosthesis fitted during life (if a name can be suggested for the deceased).
- The last issue to be dealt with before the deceased is released is that she/he be fingerprinted. A fingerprint technician should attend the mortuary and take inked impressions from each digit and area where there are ridge patterns on the deceased's hands. These fingerprints can later be used to search through criminal and civil fingerprint databases, such as the National Automated Fingerprint Identification System (NAFIS), and the digits can be used to identify the deceased.

The postmortem examination continues with items of interest being recorded by the pathologist in his/her notes and diagrams and photographically recorded by the crime scene investigator, who should use a scale rule when taking any close-up photographs. It is also at this stage of the postmortem examination that samples should be taken by the pathologist: blood for DNA profiling, alcohol determination, and drug and poison screens. Samples should also be taken for histopathology and microbiology if the forensic pathologist thinks that these are necessary.

Violent crimes typically result in a great deal of physical evidence being deposited on the deceased and the suspect and left at the scene. A thorough search should be made, as well, of the living suspect and his/her environment, for any evidence, which may be expected to be extremely transient and easily destroyed or contaminated. Depending on the type of crime, for example, shooting, stabbing, rape/murder, or blunt injury beating, different forms of evidence may be present. Additionally, the specific area on the body in which evidence is found is of extreme importance; for example, dried semen in the pubic hair of a deceased female or firearm discharge residue on and around the entry point to the chest is indicative of a contact wound. Consideration may also be given to other experts attending the postmortem examination (e.g., firearms expert).

Summary

After all the information is to hand from the crime scene and the postmortem examination, those involved should be able to work out the cause and manner of death from the facts available. In the interpretation of the cause of death, those involved must identify the initial factor(s) that may have led to a subsequent cause of death. For example, pulmonary edema can and will cause death; however, it may not be the root cause of death. Another set of circumstances, such as receiving severe burns in an explosion, may have occurred in the first instance, which led to the onset of pulmonary edema and the deceased's ultimate death.

Although modern forensic investigation is advanced, there will be times when the crime scene does not provide information and the postmortem examination does not reveal a definitive cause of death. These are the difficult cases.

Evidence Collection at Fire Scenes

JJ Lentini, Scientific Fire Analysis, LLC, Big Pine Key, FL, USA

Glossary

Accelerant Any substance, usually a flammable or combustible liquid, that is used to initiate or spread a fire.
Flash point The temperature at which a still pool of liquid will produce sufficient vapors to ignite when exposed to a competent ignition source.

Ignitable liquid A liquid that is capable of burning, often a petroleum-based product. Ignitable liquids may be flammable or combustible. Flammable liquids are those having a flash point below 37 °C. Combustible liquids are those having a flash point above 37 °C.

Introduction and Overview

Evidence collected from fire scenes can take many forms. The most common type of evidence collected at a fire scene is material suspected of containing ignitable liquid residues (ILRs). Other evidence that may be collected for ILR analysis includes comparison substrate samples, liquid samples for comparison, or suspect's clothing and shoes.

Suspected ignition sources, such as incendiary devices or appliances suspected of malfunctioning, are also frequently collected in an attempt to test the field investigator's hypothesis about the origin and cause of the fire.

The identification of an ILR in a sample of fire debris can support a field investigator's hypothesis regarding the incendiary nature of a fire. The identification of such a liquid residue in a fire scene, however, does not necessarily lead to the conclusion that a fire was incendiary in nature. Further investigation may reveal a legitimate reason for the presence of flammable or combustible liquids.

Due to the volatility of ignitable liquids and the variations in sampling techniques, the absence of detectable quantities of flammable or combustible liquid residues does not necessarily lead to the conclusion that flammable or combustible liquids were not used to accelerate the fire.

In order to have any utility, samples collected for ILR analysis must be properly packaged and labeled prior to submission to the forensic science laboratory.

Sample Selection and Documentation

In arson cases, it is common for the arsonist to accelerate the fire by pouring ignitable liquids throughout the structure. Typically, the liquids are poured on the floor, so flooring, if it survives, is what fire investigators usually sample. Selecting a sample that is likely to test positive for ILR (assuming there is any present) requires care, practice, and luck.

Where ignitable liquid has been used, it is often present in overabundance and it may be easily detectable by odor, once the floor has been cleared of fallen debris. It is also possible to see where the ignitable liquid was poured by observing the damage patterns on the floor.

On carpeted floors, there is often a distinct line between burned and unburned areas, although such lines are common

in cases where no ignitable liquid was present. Further, because of the way air is entrained into the fire plume of a piece of burning carpet, there tends to be a 'doughnut' pattern produced. This results in carpet at the center of the area saturated with ignitable liquid being less damaged than carpet at the edge of the area. [Figure 1](#) shows a typical doughnut pattern. Obviously, the 'doughnut hole' presents the best sample. When no 'doughnut hole' exists, the sample should include both burned and unburned carpet from the edge of the pattern to its middle.

On hardwood floors, ignitable liquids tend to run in the cracks, as shown in [Figure 2](#). Vinyl floors also may exhibit extra burning where the ignitable liquid has penetrated into seams or lower parts of a textured floor, as shown in [Figure 3](#).

Sample size is usually dictated by the size of the available sample containers. A sample container of 1–5 l will usually be adequate. It should be noted that because the laboratory analysis will usually involve sampling the headspace in a container, filling the container completely is not advisable. If the container is filled completely, it will be necessary for the laboratory to repackage the debris into a larger container for analysis.

When collecting samples, it is imperative that the investigator takes steps to avoid cross contamination or even the appearance of cross contamination. If the tools used for sampling are the same tools used for debris removal, those tools should be decontaminated prior to sampling using a detergent solution. Tools should be cleaned off in between samples to avoid carrying liquid residue from one place to another. If the investigator has any sense of where in the scene there is a higher concentration of ILR, that area should be sampled after the less concentrated areas are sampled.

If arson is suspected, gasoline-powered tools should not be brought into the fire scene. If power is required, a generator should be used for electric tools and the generator should be kept outside. Fire extinguishment crews should be asked whether gasoline-powered fans were used on the fire, and whether it was necessary to refuel the fan at any time. Such data should be documented.

The most important attribute of any fire debris sample is its location. When the investigator makes the decision to sample a particular area, that area should be thoroughly photographed, and the location of each sample should be documented on the investigator's fire scene sketch. Once the sample has been placed in the container, another photograph should be taken

Figure 1 'Doughnut' pattern produced by gasoline burning on carpet.

Figure 2 Burning in the cracks of an oak parquet floor.

showing both the area from which the sample was removed and the sample inside the container.

Disposable latex or nitrile gloves should be used to collect the samples and a new pair of gloves should be used for each sample. The use of gloves should be documented, preferably with a photograph of the discarded gloves at each sample location. Gloves should not be placed in the sample container.

Random sampling is not advisable. There should be a logical reason for the collection of samples. At times, this may mean nothing more than finding the location of doorways and hallways in a structure that has burned to completion.

Plastics and synthetic fibers, because of the way they respond to heat, tend to trap ILR in the melted polymer matrix. Wood flooring also tends to hold onto ILR by adsorbing the residues on the charcoal that is produced as wood burns.

Soils can retain some ILRs, particularly heavy petroleum distillates, almost indefinitely, but some residues in soils are subject to microbial degradation. Soil samples should be refrigerated if there is any significant delay (more than a few days) between collection and submission to the laboratory, or between submission and analysis. Concrete has been known to retain detectable quantities of ILR, but the overlying floor covering (if any) is more easily sampled.

In addition to his or her own olfactory senses, the investigator may employ a hydrocarbon sniffer, a mechanical device that senses hydrocarbons in the air. These devices are not very

Figure 3 Burning in the cracks of a vinyl floor.

selective, however, and should not be used in place of laboratory analysis. False positives are common.

An 'accelerant-detecting canine' is probably the most effective aid to collecting samples that have a higher probability of testing positive in a laboratory. As with any tool, canines are subject to limitations. The canine responds to scents that it has previously been rewarded for alerting to. If, on a particular scene, a canine responds to pyrolysis products, rather than foreign ignitable liquids, it is likely to respond inappropriately for the rest of the day because it has been rewarded for doing so.

Canines are incapable of identifying different ILRs. This can only be determined by laboratory analysis. There are some investigators who insist that because their canine has demonstrated extreme sensitivity, a negative laboratory test of the sample selected by the canine can be ignored. This is not true. It is the considered opinion of the scientific community (including responsible canine handlers) that canine alerts unconfirmed by laboratory analysis do not constitute valid evidence of the presence of an ILR. Some canines have confirmation rates over 90%, but others fall below 50% on a regular basis. The canine is only a tool.

One useful attribute of this tool is that the animal is willing to spend all day sniffing out a large area, something that most fire investigators are unwilling to attempt. If the scene has been properly cleared prior to the canine's arrival and there is any ILR to be found, the canine will likely find it.

Comparison Samples

Beginning in the 1980s, forensic science laboratories acquired the ability to detect smaller and smaller quantities of ILRs. The lower limit of detection dropped by at least two orders of magnitude. The result of this improved technology has been that the laboratory can now detect 'background levels' of ILR that are normal to the area being sampled. [Table 1](#) provides a list of common background materials that may be the source of ILRs. For example, the solvents used in hardwood floor-finishing products persist indefinitely in the thin polyurethane or other polymer film. For this reason, comparison samples are often necessary.

Table 1 Sources of 'background' ignitable liquids

<i>Substance</i>	<i>Potential source</i>
Toluene, xylenes, C ₃ - and C ₄ -alkylbenzenes, indenenes	Adhesives, polymer decomposition, shoes, clothing
Medium petroleum distillates and heavy petroleum distillates	Adhesives, insecticides, polishes, lubricants, magazines, newsprint, shoes, clothing, asphalt smoke, plasticizers, floor finishes
Isoparaffins	Moisture barriers, adhesives, plasticizers
Normal paraffins	Vinyl flooring, carbonless forms, copier and laser printer toner
Alcohols, acetone	Combustion products

Because the fire investigator usually gets only one chance to sample the scene, comparison samples should be collected as a matter of routine. The samples should consist of the same substrates, such as carpet, flooring, concrete, as the suspect samples. Obviously, the comparison samples should be collected from areas where, in the fire investigator's judgment, no ignitable liquid would be expected. Except in cases where there is a large excess of ILR present on the sample, the absence of a comparison sample may render a positive finding from the laboratory invalid.

Packaging Options

Fire debris samples are typically packaged in metal cans, glass jars, or plastic evidence bags specifically designed for fire debris. Each type of packaging has advantages and disadvantages.

Metal cans are usually impervious to hydrocarbon residues, are commonly available, and resist breaking. Laboratory analysts sometimes prefer cans because the cans can be heated directly in the oven. One problem with cans is that they tend to corrode over time. Fire debris tends to contain water and acids that can cause perforation of an uncoated metal can in a matter of weeks. For this reason, lined cans, the type used for water-based paints, are recommended over unlined cans. Each time an investigator purchases a new batch of cans, an empty can should be submitted to the laboratory to verify that the can lining is not contributing significantly to the extract.

Glass jars, such as Mason jars, do not corrode, but they require careful packaging to avoid breakage and the cross contamination that may result. The two-piece lids on Mason jars were not designed for hydrocarbons, and the gasket can deteriorate if exposed to high concentrations of ILR. It is recommended that the gasket be turned away from the sample.

Two-layer nylon/polyacrylonitrile-co-methacrylate-cobutadiene bags, specifically designed for fire debris analysis, are available and have been shown to make an excellent container for fire debris, assuming they are properly sealed. Research has shown these bags to be superior to nylon or polyester bags that have been used for evidence collection. The evidence bags can withstand extraction oven temperatures of up to 70 °C. The bags have the disadvantage of being subject to punctures, and fire debris often contains materials capable of causing a puncture.

However it is packaged, the fire debris should be labeled in accordance with industry practices. The label should include a unique identifier that allows a chain of custody to be established. A label on a fire debris sample should also include an identification of the person who collected it, the date it was collected, a brief description of the substrate, and a brief description of the location of the sample. More elaborate descriptions of the sample can be provided on an evidence transmittal, such as the one shown in [Figure 4](#).

Clothing and Shoes

Occasionally, law enforcement officers encounter a suspect shortly after a fire has been set and collect the suspect's clothing and shoes for ILR analysis. This can be a very useful means of linking a suspect to a fire scene, assuming it is done properly.

Clothing and shoes should be packaged separately to avoid contamination of the clothing with the background compounds on the shoes.

The left and right shoes should likewise be packaged separately. Shoes often contain significant quantities of ILRs because of the dyes and adhesives used in their manufacture. If an accelerant is splashed on an arsonist's shoes, it is unlikely that each shoe will be contaminated with the same amount. Thus, one shoe could act as a comparison sample for the other. It may be necessary to try to find a new pair of shoes of the same manufacture as the suspect's shoes, in order to determine what should and should not be present on the shoes.

Liquids for Comparison

Fire investigators will sometimes find containers of ignitable liquids at fire scenes that they wish to submit for comparison with residues extracted from test samples. This can be accomplished, but it is necessary to take affirmative steps to avoid contaminating the test samples with the comparison liquids. The liquid should be packaged and shipped separately from the test samples. Suitable containers for liquids include flint glass jars, or small evidence cans containing surgical gauze pads onto which a liquid is absorbed. Note that 'nonstick' gauze pads may contain petroleum products and are not suitable for absorbing liquids.

There are times when liquid absorbed onto a gauze pad is not suitable. Sometimes it is necessary to conduct a flash point test to determine whether a liquid meets statutory requirements. For example, some jurisdictions define a Molotov cocktail as a breakable container filled with a flammable liquid. In such a case, a sample of at least 5 ml of liquid is required and preferably 100 ml.

The laboratory procedures necessary to 'match' an ignitable liquid to a particular source are beyond the scope of this article, but readers should be aware that, except in the most unusual cases, the laboratory will only be capable of excluding a particular source, rather than positively identifying the comparison liquid as the source of the residue found on the test samples.

Figure 4 A typical chain of custody form for submission of fire debris samples to a private laboratory.**Evidence Collection for Other Types of Testing****Spontaneous Heating**

The forensic science laboratory is capable of performing other chemical and physical analyses in addition to testing for ILR.

Oily rags, suspected of having undergone spontaneous ignition, are collected and packaged in the same way as fire debris submitted for ILR analysis. The investigator needs to tell the laboratory that spontaneous heating is suspected because the analytical procedure for finding the kinds of products that undergo spontaneous heating (usually vegetable oils) is

different from the procedure used for detecting ILR. It is possible to conduct the testing for vegetable oils on the same sample used to test for ILR. ILR can be isolated using a nondestructive headspace concentration technique, and then the vegetable oils can be extracted with a solvent.

Occupancies that are subject to fires caused by spontaneous heating include commercial laundries, restaurants, and health spas, as well as buildings under construction or renovation where oil-based paints and stains are used. Spontaneous heating fires tend to occur in clothes dryers when the laundry has not been thoroughly cleansed of vegetable oils. These fires happen after

the dryer has stopped, and sometimes after the laundry has been removed and stacked. Spontaneous fires associated with painting typically occur as a result of improper disposal of rags or filters contaminated with products that contain linseed or tung oil.

Laboratory analysis for vegetable oils can only determine whether the oils are present. The laboratory analysis will not allow a determination that the oils actually underwent spontaneous heating or combustion.

Electrical Malfunctions

Most public-sector forensic science laboratories do not have in-house capabilities for examining appliances or other electrical devices suspected of causing a fire. An engineering laboratory will usually be required for such analyses.

If a product malfunction is suspected, the fire investigator is advised to ensure that any entity that might be a party to litigation has the opportunity to participate in the inspection. When possible, this should include making any suspect device available both on the fire scene and in the engineering laboratory.

The appliance or device should be fully documented on the scene and then labeled to provide a chain of custody. If there are exemplars of appliances at the fire scene, they should be collected as well. Additionally, appliances in the general area of origin, which the investigator does not believe started the fire, should be collected for purposes of elimination. Appliances and devices damaged in fires are typically delicate. Conductors and other parts may have melted or become brittle. Care should be taken to avoid further damage in the packaging and transportation of damaged appliances to the laboratory.

Laboratory inspection will usually involve the use of a magnifying glass or a stereomicroscope. x-ray examination is desirable prior to performing any destructive disassembly of the appliance or device. Real-time x-ray is usually preferable to examination with industrial x-rays and film because it can be accomplished in a more reasonable time frame.

An experienced fire investigator or electrical engineer can usually recognize evidence of electrical activity. The hallmarks of electrical activity are that the damage to the conductor is highly localized and complementary, that is, one can identify both the high-voltage and low- (or zero) voltage side of the arcing event. On small-diameter stranded wires, such as low-amperage appliance power cords, it is possible to become confused between environmental melting and electrical melting. Scanning electron microscopy is often useful, especially when different metals were involved in the arcing event.

Except in cases where a loose connection results in 'series arcing,' electrical arcs are almost always a result of an energized conductor being exposed to the fire. The insulation on the conductor carbonizes and becomes conductive, resulting in 'arcing through char.' Such arcing may help to pinpoint the origin of the fire, but it is always a result of the fire.

There is currently no valid laboratory analysis that is capable of identifying an arc that caused a fire. Scanning electron microscopy and auger electron microscopy have both been tried, but neither is accepted as valid for making the identification of an electrical arc that started a fire.

Heat-producing devices are typically equipped with safety features that, surprisingly, may survive a fire in testable form. This is because the devices are designed to withstand a hot environment. One-time fuses can be tested to see if they are electrically

open. Resettable bimetallic thermal cutoff devices can be examined to see if they are open or closed, and they can be heated with a hair dryer to determine whether they still respond to heat.

Some metals respond to heating by undergoing microscopic changes in their grain structure. These changes are capable of being identified by a metallurgist. The testing required to visualize the grain structure involves cutting and polishing a section of the metal, so appropriate steps regarding destructive testing need to be taken.

Other Forensic Analyses

Because of the destructive nature of fires, investigators often overlook traditional forensic evidence such as fingerprints, blood, toolmarks, and other kinds of trace evidence. Much of this evidence can actually survive the fire, and particularly in incendiary fires, is capable of associating a suspect with the scene.

In fatal fires, the body constitutes significant evidence. A toxicological evaluation of the victim's blood can determine whether the victim was alive during the fire. A victim with no carbon monoxide in his or her blood was probably dead before the fire began. Recent research has indicated that there is a relationship between carbon monoxide levels and the victim's location relative to the origin of the fire. Victims who die from thermal injuries because they were close to the origin typically have lower carbon monoxide levels than victims found in rooms some distance from the origin, particularly when the room of origin progressed beyond flashover.

Fire Scene Inspection Methodology

JJ Lentini, Scientific Fire Analysis, LLC, Big Pine Key, FL, USA

Glossary

Flashover A transition phase in the development of a fire in a structure, in which all combustible surfaces exposed to thermal radiation ignite more or less simultaneously and fire spreads rapidly throughout the space, resulting in full room involvement. The transition is from 'a fire in a room' to 'a room on fire.'

Fuel-controlled fire A fire in which the heat release rate and growth rate are controlled by the characteristics of the fuel, such as quantity and geometry, and in which adequate air for combustion is available.

Full room involvement A compartment fire in which the entire volume is involved in fire, but flaming will only occur when there is sufficient oxygen available.

Spoliation Loss, destruction, or material alteration of an object or document that is evidence or potential evidence in a legal proceeding by one who has the responsibility for its preservation.

Ventilation-controlled fire A fire in a postflashover compartment, where all fuels are involved, and the heat release rate of the fire is controlled by the availability of oxygen.

Introduction and Overview

Because each fire is different, specifying an exact methodology for a fire scene inspection is difficult, but there exist sufficient similarities among fires that make it necessary for the investigator to develop a standard approach. Not every step described in this article will be necessary for every fire, and many of the routine steps described can only be carried out by the 'first responder.'

Procedures will vary according to the problem a fire investigator is asked to address. Usually, the problem is to determine the origin and cause of the fire, but often there are additional questions that need to be addressed, such as the reason for a victim's failure to escape, the reason for a fire detection or suppression system's failure to function, or the reason for an unusually rapid spread of the fire.

In many cases, the origin and cause of the fire are obvious, and it is only the secondary questions that require any significant skills to address.

Although many fire investigators began their careers as firefighters, there are significant differences in the skill sets required to extinguish a fire and those required to investigate a fire. Extinguishment officers are 100% effective at putting out fires. Fire investigators, on the other hand, must sometimes accept the reality that the determination of the origin and cause is an impossible task, due to the complexity of fire behavior.

First Assumptions

More than 80% of fires are accidents, and because the consequences of declaring an accidental fire to have been intentionally set are so serious, there is a lively debate in the fire investigation community about what should be presumed. In some states, it is the law that all fires are presumed accidental until proven otherwise, but the fire investigation community has taken the position that fire investigations should be approached without any presumptions.

Planning the Investigation

It is necessary to gather sufficient information to formulate a workable fire scene inspection plan. When the assignment for an investigation is first received, the investigator needs to know what resources will be necessary to process the scene. Additionally, it is necessary to identify 'interested parties,' and to learn the use (occupancy) of a structure. Certainly, public-sector investigators have different responsibilities from private-sector investigators. Often, the public-sector investigator's work is done once the determination has been made as to whether the fire was the result of a criminal or an accidental cause.

It is often necessary to arrange for additional personnel such as fire protection engineers, or structural and electrical engineers. In commercial or industrial occupancies, heavy equipment may be required to process the scene.

It is a good idea to learn as early as possible whether there were any eyewitnesses to the fire, and whether any of them photographed or videotaped the fire in progress. If a security system exists in the building, records of alarms or even videotapes of the fire in progress may be obtainable from the alarm-monitoring company.

It is also important to ensure that the investigator has the authority and the right to enter the property to conduct the inspection. Such authority usually comes in the form of permission from the owner to enter the building, but a search warrant may be necessary in some cases.

Initial Evaluation: Can This Inspection Be Conducted Safely?

Fire scenes are dangerous places, and must be approached with caution. Because the mission of the investigator is not urgent, there is no need to compromise safety. The emergency is over. The fire has been extinguished and there is nobody to rescue. If possible, fire scene inspections should not be conducted at night. The scene should be secured until there is adequate

light to conduct the fire inspection safely and to make the necessary observations.

Obvious fire scene hazards include structural instability, energized electrical circuits, and leaking fuel gases, but there exist less obvious hazards that the investigator must consider. These include fire gases such as carbon monoxide and hydrogen cyanide, and hazards such as asbestos and biohazards.

The initial survey usually begins with the exterior of the building and then moves to the interior. It is best to move from the area of least damage toward the area of greatest damage, to avoid developing a case of 'tunnel vision,' and to make certain that all of the building has been examined by someone. It is during this initial walkthrough that the investigator can plan for the documentation and reconstruction of the fire scene. At this point, however, the investigator should avoid forming hypotheses about the fire if at all possible.

Documentation

Documentation is the most important task in a fire investigation. At some point, a jury may be asked to review that documentation and agree with the fire investigator's interpretation, but documentation is important for its own sake. Regardless of when the investigator arrives at the scene, be it minutes, hours, or months after the fire, the investigator should document the entire scene prior to making any changes.

Photographs represent the most important form of documentation, and now that images are practically free, there is no reason to limit the number of images collected. Digital cameras collect data about the order in which photographs are taken and the amount of time passed between the first and last photograph. A logical, well-organized investigation is reflected in the photographic record.

Close-up photographs are necessary in many cases, but need to be placed into context. This is accomplished by taking an overall view of the item of interest, prior to zooming in on it.

Other forms of documentation are also necessary for a proper investigation. Written notes allow the documentation of those data not suited to photography, and video images frequently help to orient the photographs.

A critical piece of documentation that is required on all but the simplest fire scenes is the sketch. In most instances, the minimum sketch should be a floor plan. Ready-made sketches may be found in the form of escape plans posted in commercial or business occupancies. A sketch is absolutely essential in order for readers of an investigator's report to understand what they are looking at. Graph paper, ruled in bold lines in 2.5 cm² and fine lines in 2.5 mm², makes the task of sketching much easier.

The level of detail required in the sketch will be dictated by the needs of the fire investigation. In many cases, a plan view showing the rooms and doorways is all that is necessary. If ventilation is an issue, and it usually is, windows are not difficult to add. If computer modeling is contemplated, however, it is not only necessary to draw the doors and windows, but to record the height of each opening, the height of all ceilings, sills, and overhangs, and the composition of the interior finish throughout. Additionally, the location of each fuel package in the room must be recorded.

Sketches should be oriented to the earth using a north arrow. An approximate scale is also essential to any sketch.

During the documentation of the scene prior to any disturbance, the investigator can make the observations necessary to help him or her decide how to reconstruct the scene. It is in this preliminary documentation that the utilities should be observed. Interior and exterior finishes can also be documented at this point. The use of a checklist of common building features is recommended so that both the important and unimportant data can be recorded. It may be that the natural gas water heater had nothing to do with the fire, but if the investigator is unable to correctly answer a question about the water heater, his credibility is likely to be impaired.

Reconstruction

Reconstruction is carried out in order to recreate, as nearly as possible, the position of various structures and fuel packages prior to the fire. Fire patterns on items that have been moved can be much more easily understood if these items are put back into place.

Although it is sometimes necessary to use heavy equipment to remove fallen structural materials, in most cases, the best tool is the flat-headed shovel. It may take ten such shovels and several wheelbarrows to remove the debris and expose the original interior surfaces. Such work is dirty and time-consuming, but it is during this reconstruction process that valuable evidence is uncovered.

The most valuable evidence is that which shows sequential data. A fire scene records everything that happened during the course of the fire from beginning to end, but most patterns do not come with time stamps. Often, the best that can be hoped for is to determine which object fell down first or what position and object was in when it was sprayed with water. Sections of ceiling material that have fallen down can be examined to determine whether there was more damage on the top or the bottom. Protection patterns caused by falling debris can also provide clues as to how the fire progressed.

Once debris has been moved, items should be placed back in their original locations, if possible. This can be particularly difficult with square or round-bottomed objects, as it is possible to reposition them exactly backward from their original location.

Once reconstruction has been completed, any portions of the scene that have been changed during the process must be documented again.

Once reconstruction is completed and documented, the fire investigator likely has all of the physical evidence there is to see. The work that has been done should allow for the development of a credible hypothesis as to where the fire started and a second credible hypothesis as to what caused it. But there are other steps that intervene.

Inventory

It is often necessary to make an inventory of the items that were present in a structure at the time of the fire. Such an inventory may serve to document the fuel load. Also, the investigator can

determine whether the inventory is consistent with the reported occupancy.

Inventory may also reveal the prior removal of contents or even the substitution of contents. The unexplained absence of valuable items or the substitution of valuable items with replacements of lesser value raises the possibility that someone had prior knowledge of the fire.

The interpretation of the inventory requires considerable caution. Fires destroy combustible items, and many of them may be completely consumed or unrecognizable after a fire. This does not necessarily mean those items were not present. It is far easier to prove the presence of an item than to prove its absence.

Avoiding Spoliation

Fire scenes are evidence, and evidence needs to be protected. This is particularly true with respect to civil cases where one party may seek to hold another party liable for monetary damages caused by a defective product or service. When an investigator reaches the point where it appears that he or she can identify a responsible party, fairness and the law require that he stop and allow the potentially responsible party an opportunity to review the evidence in place. This may require delaying further investigation for several days or even weeks, particularly if multiple parties are suspected of playing a role in causing or spreading the fire.

The fire investigation community has carefully considered the concept of spoliation, and has concluded that certain activities, such as debris removal, or opening a suspected appliance in order to identify the manufacturer should not be considered spoliation. Additionally, it may be necessary to move potentially causative agents from the scene in order to protect them from further damage.

Spoliation is an issue that is generally not applicable in criminal fire investigations, although there have been some cases where public agencies have been held responsible for allowing evidence to be destroyed and depriving a potential defendant of his right of confrontation under the sixth amendment.

Origin Determination

The determination of the point of origin is the fire investigator's most important and most difficult task. It is axiomatic that if the origin of the fire is not determined correctly, the cause will also be incorrectly determined. Generally, there are three categories of evidence that must be considered by the investigator in helping to locate where the fire started. These are:

1. Witness observations
2. The analysis of fire patterns including patterns created on the electrical system
3. The consideration of fire dynamics

Witness observations may be crucial for determining where the fire started. Particularly in the case of full room involvement, a witness statement may be the only evidence that allows the origin to be pinpointed. Witnesses may also help the investigator understand the arrangement of furniture and other items in the structure prior to the fire.

Investigators should be cautious when their interpretation based on fire patterns varies significantly from what witnesses have observed. Some experiments on the validity of origin determination using fire patterns have produced disturbingly high error rates. Other data that can be characterized as witness statements include video of the fire in progress and alarm system functions.

A word about the proper use of witness statements is in order. When determining the origin and cause of the fire, the investigator should consider only those statements that have a bearing on the fire science. The power of science in proving the truth rests on the independence of the evidence. This independence can be compromised by statements having nothing to do with the physical evidence, such as inculpatory statements made by a suspect to a third party either before or after the fire. The consideration of such statements results in contextual bias and can lead to errors in interpretation of the artifacts at the fire scene.

The mechanisms by which fire patterns are created and how they might be interpreted to lead an investigator to the origin are discussed elsewhere in this encyclopedia. Confinement patterns, movement patterns, and intensity patterns can all be useful indicators of how a fire moved. It is useful to place arrows on the sketch indicating the movement of a fire.

It is very important to consider which patterns may be the result of postflashover ventilation-limited burning, which may well have absolutely no meaning with respect to the origin.

The following is a checklist of activities to be conducted when determining the origin of the fire. This checklist follows the basic format of the scientific method.

1. Data collection
 - Basic site data
 - Determination of prefire conditions
 - Fire department information
 - Alarm, detector, and security data
 - Documentation of postfire conditions
 - Witness statements and observations
 - Excavation, examination, and reconstruction of the scene
 - Documentation of postreconstruction conditions
2. Data analysis
 - Damage assessment (Which rooms became fully involved?)
 - Fire pattern analysis
 - Heat and flame vector analysis
 - Depth of char and calcination surveys
 - Electrical arc mapping
 - Event sequencing
 - Fire dynamics considerations
 - Building construction and occupancy considerations
3. Hypothesis development
 - Initial origin hypothesis
 - Working origin hypotheses
 - Alternate hypotheses

Once an origin hypothesis has been developed, it must be tested against the evidence. There are four questions that an investigator should ask once he or she has formed a hypothesis as to the origin of the fire. These are:

1. Is there a competent ignition source at the origin?
2. Does the origin explain the data?

3. Are contradictions resolved?
4. Does an alternate origin explain the data equally well?

If there is no competent ignition source found at the origin, it is likely that the proposed origin is incorrect. The same is true for the absence of a competent fuel source at the hypothesized origin. There is a temptation on the part of some investigators to conclude that the ignition source must have been an open flame that was carried away by the person who set the fire, and the fuel source was an ignitable liquid poured on the floor, which was completely consumed by the fire. It is this type of determination that results in serious errors. In cases of full room involvement, it is often not possible to define the origin as an area smaller than the entire room.

The next question asks whether an origin in the hypothesized location explains how the fire spread from there and damaged the rest of the structure.

It is an unusual fire scene that does not contain some contradictory information. The investigator needs to attempt to resolve conflicting information; for example, if the electrical system shows signs of failure far away from where the origin is hypothesized and there is no evidence of electrical activity in the hypothetical origin. Regardless of the fire's cause, energized electrical conductors in the area of origin are likely to exhibit evidence of melted conductors.

Finally, the investigator needs to consider alternate origins that might explain the data equally well.

Cause Determination

A fire cause is defined as the circumstances, conditions, or agencies that bring together a fuel, ignition source, and oxidizer (usually air) resulting in combustion. The determination of a fire cause requires the identification of those factors that were necessary for the fire to have occurred. Those factors include the presence of a competent ignition source, the type and form of the first fuel ignited, and the circumstances that allowed the factors to come together and start the fire.

As with origin determination, cause determination must follow the scientific method. The investigator should carry out the following activities.

1. Data collection
 - Document the fuels in the area of origin
 - Document all potential ignition sources
 - Identify the oxidizing agent (usually this is atmospheric oxygen)
 - Identify the circumstances that brought the fuel, ignition source, and oxidizer together
2. Data analysis
 - Analyze the fuel (How much is present? How easily is it ignited?).
 - Analyze ignition source (Does it have sufficient energy to cause ignition? Did it exist for a sufficient period of time to cause ignition?)
 - Analyze the oxidizer, especially if other than air
 - Analyze potential ignition sequences
3. Hypothesis development
 - Propose a separate hypothesis for each potential ignition source
 - Consider absent ignition sources

Propose a first fuel for each ignition source
Consider alternate hypotheses

Once a cause hypothesis has been developed, it must be tested against the evidence. These are the questions that an investigator should ask once he or she has formed a hypothesis as to the cause of the fire:

1. Is (or was) the hypothesized ignition source located at the origin?
2. Can the hypothesized ignition source ignite the first fuel?
3. Did the hypothesized ignition source have sufficient time?
4. Is the hypothesized cause consistent with all known facts?
5. Are contradictions resolved?
6. Does another cause hypothesis explain the data equally well?

The determination of the fire's cause should be based on evidence, rather than an absence of evidence. There has been a tendency on the part of some investigators to declare that because they could find no accidental cause for the fire, it must have been intentionally set, even when there is no evidence of incendiary activity. Such determinations are referred to as 'negative corpus' determinations. Negative corpus determinations are a violation of the scientific method. The proper classification of the cause of a fire for which there is no evidence to support a classification of either accidental or incendiary cause is undetermined.

Glossary

Flashover A transition phase in the development of a fire in a structure, in which all combustible surfaces exposed to thermal radiation ignite more or less simultaneously and fire spreads rapidly throughout the space, resulting in full room involvement. The transition is from 'a fire in a room' to 'a room on fire.'

Fuel-controlled fire A fire in which the heat release rate and growth rate are controlled by the characteristics of the fuel,

such as quantity and geometry, and in which adequate air for combustion is available.

Full room involvement A compartment fire in which the entire volume is involved in the fire, but flaming will only occur when there is sufficient oxygen available.

Ventilation-controlled fire A fire in a postflashover compartment, where all fuels are involved, and the heat release rate of the fire is controlled by the availability of oxygen.

Introduction and Overview

A fire pattern, also called a burn pattern, is the visible or measurable physical changes or identifiable shapes formed by a fire effect or group of fire effects. Fire effects are the changes in or on a material as a result of exposure to the fire.

The term 'fire effects' describes the artifacts left behind by many different processes, including dehydration, melting, color changes, oxidation, charring, loss of material, alloying, spalling, expansion and deformation, annealing, soot and smoke deposition, and clean burn. Even damage to an electrical system can constitute a fire pattern. Fire investigators are thus presented with a vast array of different patterns, all of which require some level of understanding of how they are created and what they mean.

Accurate interpretation of fire patterns can lead the fire investigator to the correct origin of the fire, and hopefully, to the correct identification of the fire's cause. However, accurate interpretation is often an elusive goal.

For many years, fire investigators followed the simplistic maxim that heat rises, and fire burns up and out. While it is true that heat rises, it does so only until it reaches the ceiling. At this point, the behavior of the fire changes.

When the rising smoke and heat reach the ceiling, the upward movement is stopped and a ceiling jet is created, sending the products of combustion in a horizontal direction, which then become confined by the walls of the compartment.

A hot gas layer develops at the ceiling, and gradually, this layer becomes thicker and more energetic. It radiates heat in all directions, including downward. When the temperature of the hot gas layer reaches 500–600 °C, all exposed combustible surfaces in the room ignite more or less simultaneously. This transition from 'a fire in a room' to 'a room on fire' is known as flashover. It is the fire investigator's goal to determine the first fuel package to ignite. That ignition necessarily occurred some minutes before flashover. Postflashover burning, however, is usually far more energetic than preflashover burning, and it has the capability to obscure or even obliterate patterns that existed prior to flashover.

By visualizing the interaction of a conical plume with a vertical surface, one can understand the generation of some fire patterns. Such patterns are common fire artifacts, and often

help fire investigators determine the origin of small fires. As a fire progresses to full room involvement, however, the 'rules' of fire pattern interpretation change.

Unfortunately, many fire investigators fail to understand underventilated fires and may misinterpret the most heavily damaged area of the room as necessarily being the origin of the fire. This is explained further when ventilation-generated patterns are discussed.

Plume-Generated Patterns

Fire patterns can result from several different kinds of interactions between the fire and its surroundings. The best-understood interactions are those that occur between the fire plume and a nearby vertical surface. Such patterns are often called 'truncated cone patterns.' (Fire investigators refer to 'cones' and 'inverted cones,' but their definition is the exact opposite of the classic geometric definition of a cone. In fire investigation, the apex of the cone is at the bottom.) These patterns are typically recorded on vertical surfaces, and fire investigators look for what they call 'V' patterns.

Fire patterns evolve over the life of a fire. When the fire is new, the pattern on an adjacent vertical surface will assume the shape of the flame, and will exhibit what fire investigators call an inverted cone pattern. This triangular pattern is characteristic of young fires. [Figure 1](#) is a schematic representation of how such a pattern is created, and [Figure 2](#) shows a triangle-shaped pattern produced by a test fire. As the fire continues to grow, the pattern becomes columnar, and the sides of the pattern are roughly perpendicular to the floor. Columnar pattern production is shown schematically in [Figure 3](#) and an actual columnar pattern is shown in [Figure 4](#). Columnar patterns have a very short life span, and change as soon as the fire begins to interact with the ceiling.

Once the fire plume encounters the ceiling, or an intervening horizontal surface, a 'V' pattern is the result. A semicircular pattern is created on the ceiling. [Figure 5](#) shows how the pattern is produced when the burning fuel package is close to the wall, and [Figure 6](#) shows an actual V pattern from a fire scene. As can be seen, the schematics are quite a bit

Figure 1 Intersection of an incipient fire with an adjacent wall. Copyright 2012 from Scientific Protocols for Fire Investigation, 2nd Edition by John J. Lentini. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.

Figure 2 Triangle-shaped pattern, also called an inverted cone pattern, produced in a test fire. Copyright 2012 from Scientific Protocols for Fire Investigation, 2nd Edition by John J. Lentini. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.

cleaner than the actual patterns, and sometimes fire investigators will disagree about whether a pattern is actually a V (or half of a V).

When the fuel package burns farther away from the wall, the interaction of the fire plume with the wall occurs at a higher level, and the bottom of the intersection of the cone and the wall is not as sharp. This results in a U-shaped pattern on the wall, and a circular pattern on the ceiling. **Figure 7** shows schematically how a U-shaped and circular patterns are created, and **Figure 8** shows a classic U-shaped pattern from a fire scene. Patterns on ceilings are often more difficult to recognize, because ceilings are likely to collapse sooner than walls.

Figure 9 shows a semicircular pattern above the origin of a fire that originated inside a wall.

As a fire progresses, more fuel packages become involved, and may result in new 'V' patterns or 'U' patterns being

produced. In the past, some fire investigators have interpreted multiple 'V' patterns as evidence of multiple origins, but this is an interpretation that can rarely be justified once a fire becomes fully involved. Such interpretations are not justified in

Figure 9 Semicircular pattern on the underside of the floor above the origin. The fire originated at an overheated switch inside the wall cavity. cases of full room involvement or in any fire scene where all of the fire damage is contiguous. It is only when there is no communication between the fire patterns generated by separate fire plumes that one can state with any validity that there were two (or more) origins.

Plume pattern generation is simple to understand and explain; the difficulty lies in locating the first plume pattern generated. Further, once a compartment progresses beyond flashover, interaction with the fire plume may not be the dominant means of pattern generation on building surfaces.

Confinement Patterns

Like plume-generated patterns, confinement patterns are easily explained. Confinement patterns are caused by the hot gas layer being trapped beneath a ceiling, and interacting with the walls. The result can be either a smoke horizon or a heat horizon, depending on how well developed the fire becomes in the compartment where the pattern exists. **Figure 10** shows a smoke horizon and **Figure 11** shows a heat horizon.

Confinement patterns can provide a fire investigator with sequential data because if there is a smoke horizon or a heat horizon on a wall, then in all likelihood, that pattern was generated before the failure of the ceiling above it. This can be very useful for determining the origin in a multilevel structure, and in some cases, the confinement pattern may be the only pattern remaining. Even the absence of a confinement pattern can help to eliminate a particular level of the structure as the location of the origin.

Consider a structure where everything has collapsed into the basement. If there is a smoke or heat horizon on the basement wall, it is unlikely that the fire entered the basement late in its development. Conversely, the absence of a smoke or heat horizon in the basement tends to eliminate the basement as the origin.

A different kind of confinement pattern is sometimes produced when the heat of the fire was confined in a wall space between two vertical studs. While the pattern on the side of the wall where the fire originated may be unclear, the pattern on the opposite side of the wall may show a clear delineation of

the location of the studs. **Figures 12** and **13** show both sides of such a confinement pattern. Similarly, fires burning upward through a floor will be influenced by the structural members under the floor and patterns with parallel edges may be the result. A fire penetrating downward through the floor, on the

other hand, is unlikely to be significantly influenced by structural members below the floor.

Movement Patterns

When the fire moves from one room to another, it frequently records movement patterns at or near the doorways. An example of such a pattern is shown in Figure 14. Movement patterns are useful for tracing a fire back to its origin and for helping to eliminate the room into which the fire moved as the compartment of origin. Movement patterns typically appear as diagonal patterns moving upward from a doorway.

Irregular Patterns

Irregular patterns are typically found on floors in compartments where fires have gone to flashover and burned for some time thereafter. For decades, fire investigators thought that they could identify irregular patterns on floors as having been caused by the presence of ignitable liquids burning there. This misconception resulted from training exercises designed to teach participants to 'recognize arson.' These training exercises almost invariably involved the extinguishment of the fire before it became fully involved. In such a case, it is indeed possible to recognize a pattern caused by a flammable liquid.

Figure 15 shows such a pattern, which can be characterized as 'an obvious pour pattern.'

Figure 16 also shows an irregular fire pattern, but there was no accelerant involved in the test fire that generated this

Figure 15 Irregular pattern caused by the burning of a medium petroleum distillate on a carpet. This is a rare instance where the cause of the pattern can be interpreted as having been caused by ignitable liquids on the basis of appearance alone. pattern. This pattern was produced when the carpeted floor was exposed to radiant heat from above. The carpet failed by randomly tearing open and shrinking back in response to the heat. Some parts of the floor were protected by the carpet and other parts were exposed. The lines of demarcation between burned and unburned areas were sharp, continuous, and irregular.

It is these alternating exposure and protection patterns that occur in fully involved compartments that are capable of confusing fire investigators, particularly those who have not watched test fires burn beyond flashover. The patterns shown in Figures 17 and 18 were both interpreted by fire investigators as indicating that flammable liquids burned on the surface of the floor. Even though the laboratory samples tested negative for the presence of ignitable liquid residues, arson and homicide charges were brought against survivors of both fires. Convictions resulted in both cases.

A peer-reviewed study of test fires set with gasoline and kerosene revealed that patterns produced by ignitable liquids on floors often appear different than what fire investigators might expect. The pattern shown in Figure 19 is similar to one that an investigator characterized as ‘puddle-shaped,’ and therefore caused by flammable liquid burning on the floor. An actual gasoline fire on a similar parquet floor that resulted in a pattern with an entirely different appearance is shown in Figure 20.

The attribution of holes in the floor to the burning of an ignitable liquid on top of the floor is almost always in error.

Figure 18 This fire pattern was erroneously attributed to the burning of ignitable liquids. The unburned areas were protected by objects on the floor.

Figure 19 A 'puddle-shaped' pattern, similar to one that was attributed to the burning of a puddle of ignitable liquid. Actually, this pattern was caused by the burning of a cardboard box. Figure 20 A fire pattern on a parquet floor that was caused by the burning of 1 l of gasoline.

Ignitable liquids are incapable of existing at temperatures above their boiling point, so as long as liquid remains, the temperature on the floor will be less than the boiling point of the flammable liquid. Once the liquid has completely vaporized, there will be no more heat from that source. Arsonists use ignitable liquids to cause a fire to spread more rapidly than it would otherwise. The ignitable liquids themselves tend to burn

out very quickly, and in the greater scheme of the overall fire, provide relatively little fuel or energy.

It has been the misidentification of patterns similar to those shown in [Figure 16](#) that have caused numerous false convictions for arson.

Laboratory analysis is required to accurately identify all but the most obvious 'pour patterns,' and even in the case of obvious patterns, a laboratory analysis certainly does no harm.

Spalling

Spalling is the chipping or pitting of concrete or masonry surfaces in response to heat. The spalled area can range in size from a few square centimeters to a few square meters. Because the result of spalling is a depression in a concrete surface, spalling is often 'puddle-shaped.' For years, fire investigators attributed spalling of concrete to the intense heat generated by the burning of an ignitable liquid. This is incorrect on a number of levels. First, spalling can be caused by the differential expansion of the aggregate and the cement matrix, by the presence of steel reinforcement bars, or by the vaporization of the waters of hydration that are a part of the concrete.

More importantly, a flammable or combustible liquid burns no more intensely than other carbonaceous fuels such as wood. Burning ignitable liquids are no more likely to cause spalling than they are to burn holes in wooden floors, installing is frequently seen on surfaces where no flammable liquid could exist, such as a concrete ceiling.

Numerous experiments have been conducted to try to cause spalling using ignitable liquids, and most of those experiments have failed. On the other hand, setting a well-ventilated wood fire above a concrete floor will almost invariably result in spalling.

Electrical Damage

When a fire damages the insulation of an energized electrical conductor, the first thing that happens is the formation of carbonized insulation, which can conduct electricity from one conductor to another. The resulting current flow may or may not be sufficient to activate the overcurrent protection, that is, trip a circuit breaker or melt a fuse.

A fire investigator may observe multiple areas where this 'arcing through char' has occurred during the course of a fire. Arcing through char will leave behind artifacts in the form of globules melted copper. The first conductors that are likely to be compromised by a fire are power cords to electrical appliances. Branch circuit conductors behind walls and ceilings can also be damaged.

By noting the location of arcing artifacts on various circuits, the investigator may be able to infer the sequence of the arcing events. Certainly, all the arcing events will have taken place before the disconnection of power to the structure, and the events on a particular circuit will have occurred before the activation of any overcurrent device protecting that circuit. If a particular conductor is severed, then any arcing event that is electrically downstream of the point of severance can be logically inferred to have occurred before the event that caused the conductor to be severed.

This mapping of arcs can result in a pattern that allows an investigator to determine which parts of the electrical system were compromised first, and provide clues to the origin of the fire.

Clean Burn

Clean burn is a fire pattern on surfaces where the soot has either burned away, or was never deposited because the surface was too hot. It stands to reason that if the surface had soot deposited on it and then the soot was burned away, chances are the fire originated elsewhere. The problem of fire patterns is that they do not come with time stamps on them. If the fire begins close to a wall, it may heat the wall to the point where soot is never deposited on it, yet there is a white area that is indistinguishable from a clean burn that occurred later in the fire.

Figure 21 shows a clean burn located directly above the origin of a test fire, on the left wall between the bed and the chair. It is unlikely that there was ever any significant amount of soot deposited in the white area. Video of the test showed that the area indicated by the arrow was an area of early flame contact with the wall. The white areas to the right of the nightstand and to the right of the bed on the rear wall were actually not burned. The wall above the nightstand caught fire before the nightstand. This test fire was extinguished after only 10 s of postflashover burning. Figure 22 shows another ventilation-generated pattern from a similar test fire. It is interesting to note that the pattern assumes a V-shape, but the pattern was caused by a cloud of fuel-rich gases burning from the top downward.

Intensity Patterns

Fires produce patterns as a result of the response of materials to heat exposure. The various heat effects on materials can produce lines of demarcation. These lines of demarcation may be helpful in determining the characteristics and quantities of fuel materials, as well as the direction of fire spread.

Figure 21 Clean burns resulting from a short-lived test fire. The wall between the bed and the chair never accumulated any soot. The wall and ceiling above the nightstand were damaged by the burning of a fuel-rich cloud of smoke produced by the chair. Photo courtesy of ATF Fire Research Laboratory and Steven W. Carman, Carman Fire Investigations, with permission.

Intensity patterns may be very confusing, because of the difficulty in determining whether the pattern was caused by a fire of longer duration or of higher intensity. Attributing more intense damage to longer duration frequently will result in determining an incorrect area of origin. The test fire shown in Figure 23 was set in the kitchen, which is at the left side of the photo. Because of more fuel and better ventilation, however, there was much more severe damage in the living room, shown at the right side of the photo.

Often, fire patterns are a combination of movement, intensity, ventilation, and plume-generated patterns.

Ventilation-Generated Fire Patterns

In the early stages of a fire, the rate of heat release increases as more fuels become involved. The plumes from these burning fuel packages pump smoke and energy into a hot gas layer trapped beneath the ceiling. As the fire grows, the hot gas layer becomes thicker and hotter. It radiates heat in all directions, including downward. When the temperature of the hot

Figure 22 Clean burn resulting from a fire that burned for approximately 2 min beyond flashover. The V-shape developed from the top downward. The fire originated between the bed in the chair. gas layer reaches 500–600 °C, it radiates sufficient heat downward (on the order of 20 kW m⁻²) to ignite every exposed combustible surface in the compartment. This begins the transition phase known as flashover.

The burning of all of this exposed fuel dramatically increases the heat release rate within the compartment, but even more importantly, it consumes most of the oxygen. At this point, the fire can burn only in those places that have sufficient oxygen. This fire is known as a 'ventilation-controlled' or 'ventilation-limited' fire.

The compartment in this case is full of fuel in the form of combustible vapors, aerosols, and gases, as well as particles of unburned fuel. The entire atmosphere is flammable. In an atmosphere of air, one can create a flame by introducing and igniting a flammable gas such as methane or acetylene. If the atmosphere is methane, however, as occurs on some extraterrestrial bodies, one could create a flame by introducing a stream of oxygen. This is exactly what happens in ventilation-limited fires.

There is likely to be more intense burning around ventilation openings such as doors and windows. What has been learned lately, however, goes far beyond that and has important ramifications for the validity of fire origin determination. Patterns are likely to be created not only around the ventilation openings, but, because of the way a ventilation-limited fire behaves, they may also be created on walls and other surfaces opposite to the ventilation openings as a result of a jet of air being drawn in by the fire.

Ventilation-generated patterns can create significant confusion. Fire investigators very often will use the level and intensity of the fire patterns to determine the area of origin. The 'lowest and deepest char' is often singled out as the point where the fire must have burned the longest, but this is not true.

In 2005, agents of the Bureau of Alcohol, Tobacco and Firearms (ATF) conducted an experiment at a fire investigation seminar in Las Vegas, Nevada, to replicate similar experiments they had conducted at their training facility in Glynnco, Georgia. They built two identical rooms furnished as bedrooms, and then set them on fire and allowed them to burn for 7 min.

They then asked 53 participants in the seminar to observe the fire patterns and determine which quadrant of the room contained the origin. Three of the participants identified the correct quadrant in room number one and three different participants identified the correct quadrant in room number two. Although it was argued that some of the participants were not qualified fire investigators, and that time and resources were limited and investigators were not allowed to touch the evidence, the low success rate of the participants was a cause for concern.

The ATF agents conducting the experiment formed a hypothesis that the amount of postflashover burning would influence the investigator's ability to correctly identify the quadrant of origin. The experiment was repeated with some modifications.

In 2007, three burn cells were constructed in Oklahoma City, and 70 fire investigators were asked to identify the quadrant of origin. In the first burn cell, the fire was allowed to burn 30 s beyond flashover, and 64 of 70 investigators correctly identified the quadrant of origin.

In the second burn cell, the fire was allowed to burn for 70 s beyond flashover. In this case, six investigators declined to

identify the quadrant of origin but of the 64 who did attempt to identify where the fire started, only 44 correctly identified the quadrant of origin.

In the third burn cell, the fire burned for 3 min beyond flashover. Seventeen investigators declined to make a determination. Of the 53 investigators who responded, only 13 correctly identified the quadrant of origin. This amounts to a 75% error rate, which is no better than if 53 untrained individuals had picked the quadrant of origin at random. Clearly, these snapshots of origin determination accuracy indicate that there are serious problems with the training of fire investigators.

In an effort to understand what was causing the confusion, the experimenters reconstructed three burn cells at the ATF laboratory Fire Research Laboratory in Amundale, Maryland. The burn cells were equipped with thermocouples and radiometers and the burning was carefully monitored. The results indicated that what was happening was that the fire was burning most intensely at a point directly across from the single opening, a doorway, as a result of the vitiation (lack of oxygen) of most of the compartment and a jet of clean air coming in at the bottom of the door.

The test fire was modeled using FDS (fire dynamics simulator) and the output was translated using smokeview, a program that allows visualization of the numerical output of the model. Figure 24 shows that the radiant heat flux opposite the doorway was 150 kW m⁻² on the wall. Figure 25 shows a 'slice' of the smokeview output, where red indicates oxygen at a concentration of 21% (air) and blue indicates a concentration close to zero.

These results help us to understand what is happening in the production of fire patterns after flashover, but far more research is needed. This was a simple test with a single opening and a single compartment. Simple tests similar to this are necessary to understand what is happening, but the conditions of this test seldom obtain in a typical structure fire. Many times, the initial ventilation source (before the windows break) is from inside the structure. Many times, there are multiple ventilation sources, especially after the windows break.

The consumption of all the oxygen in the room can cause the fire at the origin to burn much more slowly there than elsewhere. If the origin is located in a place where a ventilation-generated pattern is overlaid, then information about the origin may be lost.

Fire investigators' confusion about how to correctly locate the origin of the fire is not a trivial matter. It is generally accepted that if one does not correctly identify the origin, one is likely to incorrectly identify the cause. Even more concerning is the fact that when a fire investigator identifies an area of origin and then finds no competent ignition source or even a competent fuel source in that area, he is likely to conclude that the fire was set using an open flame that was removed from the scene, and that the initial fuel was an ignitable liquid or some other highly flammable fuel that was introduced and completely consumed. A false determination of arson is likely.

This is new knowledge for many fire investigators, and upon being confronted with it, they are likely to reject the scientific basis of the experiments and insist on their ability to determine an origin even in a fully involved compartment.

What should happen is that once a compartment is identified as having been fully involved, every potential ignition

Figure 24 Smokeview output of an FDS model, showing the effects of ventilation. The fire originated to the right of the headboard, but air flowing in through the bottom of the door resulted in a radiant heat flux of more than 150 kW m^{-2} on the wall opposite the door. Figure 25 Smokeview slice showing the oxygen concentration in the plane of the door. Photo courtesy of ATF Fire Research Laboratory and Steven W. Carman, Carman Fire Investigations, with permission.

source in that room should be examined, unless there is some compelling evidence that allows the origin to be narrowed further than the entire confines of the compartment. An eyewitness to the beginning of the fire or perhaps a videotape of the fire might meet these criteria. Certainly, the simple traditional interpretation of fire patterns in such a situation is likely to lead to error.

Glossary

Backdraft An explosion resulting from rapid/sudden influx of oxygen into a oxygen deficient area containing superheated products of an incomplete combustion reaction.

Combustible liquids Combustible liquids have flash points that are greater than 100° F.

Combustion products Heat, gases, solid particulates, and liquid aerosols produced by burning.

Conduction Heat transfer to within an object or to another object by direct contact.

Convection Heat transfer by circulation within a medium such as a liquid or gas.

Fairies Light mass combustible material that ignites while floating on air currents prior to ignition of heavier mass/larger materials. In certain instances, if large quantities of this type of material are present, it can lead to an explosion.

Fire point Refers to the temperature at which a material gives off enough vapors to sustain combustion. This is usually slightly above the flash point temperature.

Flammable liquids Flammable liquids have flash points that are less than 100° F.

Flammable/explosive limits This refers to a concentration range where too little fuel will not support combustion and too much fuel will displace oxygen that will prevent the

reaction from taking place. There are exceptions that can occur when a fuel supplies its own oxygen.

Flammable/explosive range This refers to the range in which materials can then ignite and either combust or explode. This range will vary depending on the flammable material in question.

Flash point This refers to the lowest temperature at which a liquid (or in some cases a solid) will give off vapors that can ignite in combination with oxygen.

Fuel A material that yields heat (i.e., energy) as a result of combustion.

Ignition temperature The ignition temperature of a substance (solid, liquid, or gaseous) is the minimum temperature to which the substance exposed to air must be heated in order to start combustion.

LEL/UEL (LFL/UFL) Lower explosive (flammability) limit/upper explosive (flammability) limit. These are the upper and lower limits of the flammable range.

Pyrolysis The changing of material into other compounds by heat. In many instances, this process can precede actual combustion.

Vapor density Vapor density is a term used to describe the weight of vapors. The weight is always referenced against air which has density of 1. Lower densities rise, while greater densities sink.

Theory of Fire

The chemical reaction of fire, or combustion, is actually an oxidation reaction. Oxidation is the chemical combination of oxygen with any substance (rust is an example of oxidized iron). Very rapid oxidation of a substance is called combustion or fire. Complete combustion occurs when materials burn in oxygen and they can produce by-products that are limited by the fuels involved in the process. If a hydrocarbon combusts, carbon dioxide and water are the products produced. Oxides are the most common by-products when certain types of elements combust. Examples would be: carbon to carbon dioxide, nitrogen to nitrogen dioxide, iron to iron oxide, and sulfur to sulfur dioxide, to name a few.

The most visible part of a fire is the flame. It is produced as the fuel burns/combusts. The color of the flame is sometimes dependent on the temperature of the fire; however, there are other factors that can cause different colors to appear in the flames. Certain materials will impart specific colors to the flame. Because of this, flame color cannot be considered as a definitive indicator of temperature (Tables 1 and 2).

Another visual product of fire is smoke. Smoke is an unwanted by-product of fire. It is a mixture of solid/liquid particulates and gases that can be released when a material undergoes combustion or pyrolysis. The items mix with air

and become airborne. Different materials can produce different colors of smoke during combustion (Table 3).

As the temperatures rise above the ambient temperature of a material, pyrolysis takes place. Pyrolysis is the chemical decomposition of matter through the action of heat. It can take place in the absence of oxygen. Pyrolysis is derived from the Greek phrase 'pyr' meaning fire and 'lysis' meaning separating and literally means to separate by fire.

Fires, as previously stated, are a chemical reaction. This type of reaction is exothermic (produces heat) and has several distinct characteristics:

Decomposition – Fire causes a decomposition of the material 'burning' into other products. This decomposition of combustible material slowly gives off gases including water vapor (these combustible gases are not ignitable during the early stages of combustion process). The gas evolution (i.e., production) continues with some of the gas becoming ignitable (as the temperature increases the gas production also increases). As the temperatures and gas production increase, the reaction speeds up and eventually becomes self-sustaining as long as suitable combustible materials are present.

Heat – As stated earlier, fire is an exothermic reaction. Early man made use of this to keep himself warm and cook food. Heat as it relates to fire is how fire is propagated. Once enough heat is applied to an object, it will generally start to burn.

Table 1 Flame color during combustion vs. temperature

Faint red	900° F
Blood red	1050° F
Dark cherry red	1175° F
Cherry red	1365° F
Salmon red	1650° F
Orange	1725° F
Light yellow	1975° F
White	2200° F
Blue white	2550° F

Table 2 Flame color from chemical compounds

Crimson	Strontium
Yellow	Sodium
White	Magnesium
Green	Boron
Blue	Copper
Purple	Potassium
Red	Rubidium

Table 3 Smoke color from combustion

Vegetation	White
Wood	Gray to brown
Paper	Gray to brown
Cloth	Gray to brown
Gunpowder	Yellow to brownish yellow
Petroleum products	Black

However, in order for this to occur, the heat energy must be transferred to the 'target' material so that combustion can occur.

Transfer of heat – There are three ways to transfer heat energy: conduction, convection, and radiation.

Conduction is the transfer of heat through molecular activity within a material or medium. Usually it is in reference to a solid. Generally, items must be in direct contact with another for conduction to take place.

Convection is different from conduction in that it is a transfer of heat energy by a circulating medium, such as a gas or liquid. This transfer of heat energy is more widespread than in conduction and objects need not be in direct contact. This also includes boiling liquid evaporation explosions (BLEVES).

Radiation transfers heat energy by way of energy wavelengths. These wavelengths of energy move in the same way a light does. These 'rays' travel in straight lines and when strike an object, are absorbed or reflected by the surface of the object.

Physical States of Fuel

The fuel necessary for a fire can be found in three different states of matter:

Solid – Solids have a definite shape and volume. They can easily be measured. Their combustibility is in direct proportion to their surface area available for combustion. For example, a solid block of wood is much harder to burn than if it is reduced to sawdust. In this instance, the sawdust can burn (i.e., combust) at such a rapid rate that it can actually cause an explosion. It should be noted, however, that in all

**Figure 1**

actuality, solids themselves do not burn. They must be converted to combustible gases first.

Liquid – Liquids will assume the shape of their container. They exhibit a definite volume. If left out and uncovered, they can evaporate (turn to a gas). Liquids also exhibit two properties referred to as flash point and fire point. The term 'flash point' means lowest temperature at which a liquid (or in some cases a solid) will give off vapors that can ignite in combination with oxygen and 'fire point' means temperature at which a material gives off enough vapors to sustain combustion.

Gas – Gases are those materials whose molecules are in constant rapid and random movement. These materials have no definite shape or volume. They assume the constraints of their current container. Gases have the ability to be compressed or expanded, dependent on their surroundings. Their volume is directly dependent on pressure and temperature. An increase or decrease in temperature will cause a proportional increase or decrease in volume if the pressure remains constant. An increase or decrease in pressure will cause a proportional increase or decrease in volume, if the temperature remains constant. Gases are also able to diffuse. This term refers to their ability to uniformly distribute their molecules through another substance. This ability is measured by their vapor density. Air has a VD of 1. Gases also are permeable. This is the ability of other materials to pass through or permeate a gas.

The Fire Triangle

The old theory of fire utilized what was called the 'fire triangle.' The triangle was originally composed of three sides: Fuel, oxygen, and heat. All three must be present in order for 'fire' to occur (see diagram below). Remove any one 'side' and fire goes out. Pour cold water on a camp fire and you are removing heat and sometimes oxygen. Spray carbon dioxide on a fire and you are removing the oxygen (Figure 1).

The Fire Tetrahedron

The new theories of fire have built on the fire triangle and have replaced it with the fire tetrahedron. It consists of four components: fuel, oxygen, heat, and chemical reaction (Figure 2).

The new theory of fire addresses the actual chemical reactions that take place producing combustion or fire. This theory was developed with the advent of chemical extinguishers that disrupt the actual chemical combustion process.

Figure 2

Classes of Fires

Fire/combustion can be broken down into several distinct classes or types. They are as follows: Class A, Class B, Class C, and Class D

Class A fires are fires in 'ordinary' materials (organic materials) that can burn to ash. The combustible materials that fall under this type of fire include wood, trash, nonmelting plastic, rubber, paper, and cloth. These fires are generally dealt with by cooling the fire below its ignition temperature. Class A fires can be extinguished with a water fire extinguisher, which contains air-pressurized water that will successfully snuff out flames as it cools down the combustible materials.

Class B fires occur in flammable substances that do not leave embers or ashes when they combust. These materials include gasoline, jet fuels, propane, paint thinner, kitchen grease kerosene, oils, paint, turpentine, grease, tar, and so on. Class B fires are extinguished by providing a barrier between the burning substance and air or oxygen. Class B fire require the use of a dry chemical or a carbon dioxide fire extinguisher to put it out. Dry chemical extinguishers contain foam or powder, while carbon dioxide extinguishers contain highly-pressurized carbon dioxide. Utilizing a Class A extinguisher would merely spread a Class B fire.

Class C fires occur in live electrical materials. These types of fires involve electrical equipment. Class C combustible materials include electrical outlets, appliances, circuit breakers, and wiring. As with Class B fires, the best way to suppress a Class C fire is to remove the oxygen. Some type of nonconducting extinguishing agent is necessary to put out these types of fires. If any of the other types of extinguishing agents are used, there is the possibility of an electrocution hazard being produced if a Class A extinguisher is used. Use dry chemical or powder fire extinguishers when confronting Class C fires instead of a carbon dioxide fire or Halon extinguisher on a Class C fire involving electronics, such as TVs and computers, because a powder extinguisher can leave a damaging residue and these types of extinguishers do not.

Class D fires are those that involve combustible (i.e., reactive) metals, such as titanium, magnesium, aluminum, zirconium, sodium, potassium, lithium, and so on. The greatest

hazard exists when these metals are in the molten state or in finely divided forms of dust, trimmings, or shavings. These types of fires are best extinguished by covering the combusting material with a special dry powdered or granular materials that exclude oxygen and do not react with the combusting metal. Class D fire extinguishers often contain sodium chloride, graphite-bearing compounds, or sodium carbonate. A powdered copper metal fire extinguisher on a Class D fire involves lithium and lithium alloys. Class D fires do not react well to water and in many cases the water may increase the intensity of the fire. It can be very dangerous to attempt to put out a Class D fire with an extinguisher that is not labeled as a Class D.

A fifth class, Class K fires, has been noted by some. These types of fires involve some type of cooking oil or fat. This class is common in the UK and referred to as Class F fires. However, in the US, these materials are listed as fuels in Class B fires.

Phases of Fire

Fire can be in any of several phases or forms. The *Incipient* phase can last from mere seconds to days. This phase is dependent on the type of fuel and ignition source. The *Emergent* phase may show slightly elevated levels of combustion products. There are no real open flames at this point. *Free* or *open burning* will show open flames and also show a rapid rise in temperature. At this point, 'flashover' can occur throughout the room. Shortly before this happens, 'Fairies' will occur indicating flashover is ready. All fires are controlled by oxygen and fuel. Low oxygen levels can cause the fire to become semi-dormant until more oxygen is introduced, while shortages in fuel can actually extinguish the reaction.

Counterfeit Goods

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Authentic goods Goods produced by a manufacturer who purports to make them.

Counterfeit A product produced to be taken as the authentic product.

Fourth shift Products produced illicitly in the same factory that produces the authentic products, using inferior materials or even the same materials as the authentic.

Knock-off A product produced to be similar to an authentic product.

Introduction

Authentic goods are produced by a manufacturer who purports to make them. Authentic goods, or 'authentic,' can be either licit, legitimate products on the open market, or illicit, illegal products sold clandestinely, such as heroin or methamphetamine. Authentic goods present opportunities to criminals and others to simulate them through unauthorized production methods for financial gain. These unauthorized products generally take one of two forms. The first is a *counterfeit*, a product produced to be taken as the authentic product, for example, a nonauthentic purse being sold as a *genuine* Hermes purse. Other forms of counterfeiting include forgeries (as in art, documents, or signatures), fakes (a real object that has been changed in some way to convince others that it has or has not been altered), and plagiarism. Note that an authentic illicit product can still be counterfeited: tablets containing no active ingredients can be disingenuously sold as genuine but illegal ecstasy, for example. The second form is a *knock-off*, a product produced to be *similar* to an authentic product. For example, a purse designed to *look like* a Hermes purse but with obvious traits or characteristics missing and does not purport to be an actual Hermes purse.

Media traditionally portray counterfeits of luxury goods, such as expensive watches, purses, and shoes, as sold in flea market stalls or out of automobile trunks. In reality, luxury counterfeits compose only about 4% of the total counterfeit market. Any good or product can be counterfeited and no product is too inexpensive to escape notice (Figure 1). Pharmaceuticals, aircraft parts, shoe polish, foodstuffs, construction materials, military materiel, movies, alcohol, music, and toothpaste are all examples of genuine products that have been counterfeited. Each year, customs officials seize hundreds of thousands of counterfeit goods and destroy them (Table 1).

Counterfeits, for many reasons, are not produced to the same standards as authentic. The main reason is economic: If a product can be manufactured illegally for a fraction of the final sales price and the risk of arrest, conviction, and imprisonment is minuscule, the financial reward appears to be worth the minor chance of punishment. The economics of counterfeit production are staggering. In one example, a group imported fake watch parts from China at a cost of \$0.27 per watch. The group sold the assembled watches to wholesalers for between \$12 and \$20 per watch, a profit of between 4344% and 7307%. The wholesalers sold the watches to street

dealers and vendors for \$20 to \$35 per watch, for a profit of between 67% and 115%. The watches were sold by the vendors at bargained prices with customers, sometimes selling as high as \$250. Globally, this represents an enormous economic loss to businesses, somewhere around \$600 billion annually. By comparison, WalMart's market value is around \$168 billion.

The lack of quality in counterfeits constitutes the greatest risk to the end user, as it results in product failures, lack of effectiveness or intended effect, or health risks and even death. For example, somewhere between 10 000 and 200 000 people die every year from counterfeit pharmaceuticals, either because of a lack of intended effect (the counterfeits did not have the purported active ingredients) or the counterfeit contained poisonous materials (such as road paint or concrete, which have been found in counterfeit pharmaceutical tablets). Many hundreds of thousands more are hurt or suffer health problems due to counterfeits or knock-offs, as in the incidents of melamine found in Chinese milk (the melamine created a positive result on a necessary quality check), which led to sickness in 300 000 children in 1 year, or strontium in housing drywall made in China (two to ten times greater than US-made drywall).

Most counterfeit goods are produced in China and counterfeiting is thought to account for 8% of China's gross domestic product; 66% of US Customs seizures are of goods from China. Hong Kong (14%), Jordan (4%), and other countries (16%) are also top counterfeit producers. Some counterfeits are produced in illegal or makeshift factories, but others are produced in the same factory that produces the authentic products, using inferior materials or even the same materials as the authentic (so-called fourth shifts). Hazardous conditions are common in counterfeiting production sites, as is child labor, forced labor, and human rights abuses, not to mention low pay, usury, and violence.

Counterfeiting is not only a criminal and public health issue but also one of national security. The United States Department of Commerce released a study in 2010 that found counterfeit parts are involved in nearly 40% of the Pentagon's parts supply chain. The problem is on the increase, rising from 3868 incidents in 2005 to 9356 incidents in 2008. Instances of counterfeit body armor and automotive parts affect law enforcement officers and their safety as well. Between amateurish and professional efforts, it is generally estimated that every US \$1 in \$12 500 is counterfeit. The US \$100 'supernote' counterfeit currency is thought to be an attempt by a foreign power to

Figure 1 An authentic Sharpie Brand pen next to a counterfeit 'Shoupie' brand pen. Source: Creative Commons 3.0, open source.

destabilize the United States economy with extremely well-made counterfeit currency. This is not a new idea. The Nazi SS planned to destabilize the British economy during World War II with Operation Bernhard, by dumping £134 billion in excellent quality counterfeit pound notes over England; the plan was scrapped when it was found that the *Luftwaffe* did not have enough planes to deliver the bills.

Profits from all counterfeit goods fund organized crime or terrorism at some point. Drug cartels, terror groups, and triads generate enormous profits to fund other legal and illegal enterprises. Money laundering is key to the success of criminal enterprises and complicit consumers who knowingly purchase counterfeits through flea markets or bodegas unwittingly assist in the generation of legitimate funds for criminals and terrorists. Because of this, counterfeiting has been called a 'consumer problem' and is seen as a matter of educating the public on the criminal issues surrounding the production of counterfeits and not merely the economic loss to luxury goods companies.

Counterfeits as an Insight to Classification

Evidence is initially categorized much as in the real world, that is, based on natural taxonomies (*Genus species*) or the taxonomy created by manufacturers. Forensic science adds to this taxonomy to further enhance or clarify the meaning of evidence relevant to the goals and procedures of the discipline. Forensic science's taxonomies are based on – but different from – production taxonomies. Manufacturing of economic goods, for example, creates its taxonomy through analytical methods. Set methods ensure a quality product fit-for-purpose and sale. The taxonomy is based on the markets involved, the orientation of the company production methods, and the supply web of raw and process materials. Explicit rules exist on categories created by manufacturers and recognized by consumers.

Forensic analytical methods create augmented taxonomies because the discipline uses different sets of methods and forensic scientists have different goals. Their taxonomies are based on manufactured traits, aftermarket qualities, intended end use, and also 'as used' characteristics. The 'as used' traits are those imparted to the item after purchase either through

Table 1 Commodities seized by US Customs and Border Security, Department of Homeland Security, and their dollar value in US\$ in 2009

Figure 2 Simvastatin tablets imported via the Internet, color images and near-infrared spectroscopic images (active ingredients are seen as bright spots). (a) Merck, Inc. (manufacturer); (b) Mexico; (c) Thailand; (d) India; and (e) Brazil. Reproduced from Veronin M and Youan BC (2004) Magic bullet gone astray: Medications and the internet. *Science* 305: 481.

normal or criminal use. Forensic science has developed a set of rules through which the taxonomies are explicated. For example, forensic scientists are interested in the size, shape, and distribution of delustrants, microscopic grains of rutile titanium dioxide incorporated into a fiber to reduce its luster. The manufacturer has included delustrant in the fiber at a certain rate and percentage with no concern for shape or distribution (but size may be relevant). The forensic science taxonomy is based on manufacturing taxonomy but is extended by incidental characteristics that help us to distinguish otherwise similar objects.

Both production and forensic taxonomies lead to evidentiary significance because they break the world down into intelligible classes of objects related to criminal acts. Counterfeits also add to these taxonomies, although are neither purely manufacturer nor forensic-based. Implicit in the recognition of a counterfeit good, however, is the definition of the authentic product; unless an authentic definition exists, a product cannot be produced clandestinely. For example, [Figure 2](#) shows Simvastatin tablets, in color and near-infrared spectroscopic images, imported via the Internet. The variations in composition, constituents, shape, and consistency would all lead to exclusion from the legitimate source (Merck, Inc., the actual manufacturer) in a comparison examination scheme. Although (b), (d), and (e) are round tablets, differences in their manufacturing parameters – essentially quality control – lead to distinct differences that are easily seen with a visual examination under near-infrared light (the bright spots are active ingredients). Therefore, the manufacturing supply chain and production processes provide the basis for differentiation. Moreover, it is possible to create a definition of the authentic product from descriptions of the counterfeits (based

on what is present, what is lacking, the qualities and quantities of these traits, and others). Manufacturers may be hesitant to provide product descriptions to forensic scientists because of perceived threats to ‘trade secrets.’ Knowledge of authentic products is important not only for examination of counterfeits but also to enhance the forensic scientist’s understanding of the authentic products under study.

Glossary

Feathering A term used to describe small ink extensions along the edge of an intaglio printed image. These are caused by some of the ink being forced into the spaces between individual paper fibers from the extreme pressure of the intaglio printing process.

Intaglio A printing technique in which the reversed image is incised into the surface of a printing plate. This technique produces a raised image on the printing surface.

Letterpress A printing technique in which a reversed, raised image on a printing plate is inked and applied to the printing surface.

Offset lithography A printing technique in which the inked image is transferred from a printing plate to a rubber blanket and then to the printing surface.

Optically variable device An image that exhibits various optical effects such as movement or color changes.

Planchettes Distinctive, small disks added to paper stock during the papermaking process. These disks can be made of a variety of materials and may possess properties allowing them to serve as security features.

Thin-layer chromatography A technique used to separate a mixture into its components using a sheet of glass or plastic that is coated with a silica gel.

Genuine Currency

To successfully determine if a banknote is counterfeit, the characteristics of the corresponding genuine banknote must be understood. Genuine banknotes are mass produced to a set of standards and specifications while no such standards exist for counterfeits. Identifying a counterfeit is done by confirming that it does not meet the specifications of a genuine banknote.

The materials and methods used to produce genuine currency are selected for their difficulty to counterfeit as well as for their durability. Banknotes will go through extensive handling and equipment processing during their lifetime, so it is vital that the materials used be able to withstand these treatments along with routine wear and tear due to circulation. Materials are selected for their distinctiveness and are often manufactured specifically for security documents and are not commercially available. The printing of banknotes utilizes the traditional printing processes such as intaglio, typography, and offset on high-quality rag paper or polymer substrates. The specialized security inks are also selected for their durability and functionality within the overall banknote design.

Genuine Currency Substrates

Traditionally, the substrate chosen for banknotes has been a highly durable, uncoated, ultraviolet (UV)-dull rag paper made from either cotton or linen or a combination of the two. Fillers, binders, and other distinctive materials, such as security fibers or planchettes, can be added during the papermaking process for added security and durability. These materials may be natural or synthetic and help distinguish the security substrate from commercially available paper stock. Security fibers or planchettes may contain materials for overt, covert, or forensic identification.

There are other types of security features that can be inserted during the papermaking process. These features may be embedded entirely in the paper or weave in and out of the paper

for a windowed effect. The most common of these is in the form of a security thread which can also contain additional properties such as UV fluorescence or the appearance of movement as well as machine-readable features to assist with authentication. Security watermarks are another feature that can be incorporated during the papermaking process. Traditional portrait watermarks are created by depositing paper fibers in varying densities to produce a shadowed appearance. Electrotype watermarks are created by reducing paper thickness in determined areas to produce lighter areas and increase the visibility of the desired image within the paper.

As technology has advanced so has the sophistication of the substrates available for use. Polymer substrates have advanced and offer a durability advantage over paper substrates. Polymer substrates are resistant to tears and folds because of its non-porous and nonfibrous composition. Polymer substrates can incorporate the same security features as paper substrates; however, there are additional security features that can be incorporated into polymer that are unavailable to paper. One of these is a transparent window containing an optically variable device.

Genuine Currency Printing Processes

The three printing processes commonly used to produce genuine currency are intaglio, letterpress, (typography), and wet or dry offset. Screen printing may also be utilized to apply specialized features. Any combination of these printing processes can be found on most currencies.

Intaglio

Historically, intaglio printing has been used for engraved artwork, invitations, and banknotes. The image that was to be printed was engraved by hand into a metal plate using lines and dots of varying length and depth. A very opaque, viscous ink is forced into the engravings, while the plate surface is kept clean. The high pressure of an intaglio printing press forces the substrate into the engravings where it adheres to the ink and

the image is transferred. This type of printing is desirable for security documents such as banknotes because of its unique characteristics. The thick intaglio ink will produce an image with a raised, embossed texture that is extremely difficult to achieve using other methods of printing. Another unique characteristic of intaglio is the 'feathering' it produces along the edges of printed areas. These patterns of ink spread along individual paper fibers, along with the tonal qualities that intaglio is capable of producing, help give the image area a more life-like appearance (Figure 1). Advances in technology have led to the use of computer-assisted laser devices to engrave the intaglio plates.

Letterpress (typography)

Letterpress printing involves applying ink to a raised surface which is then transferred to the desired substrate by direct impression. One of the characteristics produced by this method is a slight indentation or embossing of the paper from the impression. Another characteristic is the slightly darker and thicker outline of a letterpress image area due to the excess ink being squeezed toward the edge (Figure 2). This type of printing is typically used to add unique identifying information to banknotes such as serial numbers.

Offset

Offset lithography is a flat printing process with none of the characteristics typically found in intaglio or letterpress images. This style of printing is commonly used in commercial industry for printing high-volume items such as newspapers. Wet offset produces images on a flat, metal printing plate for single color printing. Chemical differences between the image and nonimage areas allow for the image areas to accept ink and the nonimage areas to resist ink. Unlike most traditional printing processes such as intaglio and letterpress, where the printing plates come into direct contact with the substrate, offset is an indirect printing process. The ink is first transferred from the printing plate to a transfer plate or 'blanket' and then to the desired substrate.

The main characteristic of offset printing is that the image area appears sharp and even with very crisp lines and edges (Figure 3). There will not be any 'feathering' as seen with

intaglio or a dark outline due to ink build up as often seen with letterpress. Because it is an indirect printing process, there will not be any embossing of the substrate from contact with the printing plate.

While offset printing is used commercially for a variety of items, it allows for additional layers of security in the printing of documents such as banknotes. More advanced offset presses are capable of exceptionally tight registration between images on the front and back of the document as well as the ability to print extremely fine interwoven lines of varying color saturation. This produces images with qualities that are very difficult for counterfeits to reproduce whether using traditional or digital methods.

Dry offset is another form of offset printing that uses a raised image area but still utilizes the transfer 'blanket.' Images produced this way may have some of the same characteristics of letterpress but the substrate will not demonstrate any signs of embossing.

Screen printing

The screen printing process uses a stencil and screen to produce images. Ink is forced through the screen onto the substrate. The ink used is very thick resulting in a slightly raised image; however, the pattern of the screen can sometimes be seen along the edges of images produced with this process and because no considerable pressure is applied, the substrate will not demonstrate any embossing (Figure 4). Screen printing is commonly used to apply specialized optically variable features to banknotes.

Figure 1 Genuine intaglio printing on US currency.

Figure 2 Genuine letterpress (typography) printing on US currency.

Figure 4 Genuine screen printing on Euro banknote.

Applied Security Features

The security of a banknote is only as good as the security of the design. There are many options for features that can be incorporated into the design. Holographic features are widely used in many security documents including currency and are a challenge for counterfeiters to simulate.

Currency Authentication

Authenticating any document requires an understanding of the genuine and the security features it should contain. This means the quality of the genuine production process is vital to ensure a product that can be consistently recognized and authenticated as genuine. Natural variation can occur in any production process but these variations must be understood and documented to eliminate any confusion. If a banknote does not fall within these known ranges of variation, then it can be determined to be counterfeit. Experienced cash-handlers scrutinize banknotes for their security features and will recognize variations in quality very easily while someone less experienced may simply rely on the image. Counterfeiters can take advantage of untrained individuals by creating a counterfeit with high image quality but lacking in many of the other security features that a trained cash handler would check.

Machine authentication of banknotes utilizes specific features in the currency designed to be machine readable. If a counterfeiter's goal is to defeat these types of authentication devices, they will often focus their attention on these machine-readable features and ignore the quality of the image on their counterfeit.

Counterfeit Examinations

Microscopy continues to be the most advantageous method for examining suspect counterfeit banknotes. The magnification can range from 7 to 40 $\times$ for observation of security features and printing process characteristics allowing for retail establishments to have a small, handheld magnifier, such as a linen tester, to check suspect counterfeits. More complex examinations, such as paper fiber assessments, will require higher magnification from 40 to 100 $\times$ and are often reserved for the forensic document examiner or counterfeit specialist. Alternate light sources ranging from the near infrared to the UV are also necessary. More extensive examinations can be performed with specialized equipment that requires operator expertise but can lead to valuable forensic and investigative information.

Physical Examination with Light Sources

Physical examination of the suspect counterfeit can first be done using standard and transmitted light and a direct comparison to a known genuine image. Standard reflective light allows for the color and presence of overt security features to be evaluated and compared. Using reflective light at an oblique angle will allow for the viewing of the substrate's topography as well as observation of optically variable features such as optically variable ink (Figures 5 and 6).

Transmitted light allows the examiner to view embedded security features such as threads and watermarks which by design should only be able to be observed with transmitted light (Figures 7–10). Any misalignment of front-to-back registered features can also be detected using transmitted light and may be the indication that a suspect banknote is counterfeit.

UV light sources allow the examiner to observe the UV brightness of the suspect substrate. While most commercial papers have optical brighteners added to them, currency paper substrates inherently possess a UV-dull response. Post-issuance chemical exposure however can result in genuine currency

Figure 5 Genuine optically variable ink (OVI) copper color on US currency.

Figure 6 Genuine optically variable ink (OVI) green color on US currency.

Figure 7 Genuine embedded security thread.

Figure 8 Security thread simulated by printing on counterfeit US currency.

Figure 9 Genuine security watermark.

paper substrates obtaining a UV response, so this examination should always be combined with other examinations to confirm if a banknote is counterfeit. Security features incorporated into banknotes may also possess UV properties. A UV light source will allow the examiner to determine if UV properties are present but can also reveal simulated security features on counterfeit banknotes (Figures 11–13). Since the materials used to print these simulated features will often absorb or reflect UV light, they can be viewed in a distinguishable manner from genuine substrates.

Figure 10 Security watermark simulated by printing on counterfeit US currency.

Figure 11 Genuine ultraviolet response.

Physical Examination with Microscopy

Microscopy is one of the most valuable tools an examiner can use when conducting physical examinations of suspect counterfeit banknotes. Paper substrate composition, security features, and side-by-side comparisons of the intricate banknote design can all be done with various microscopy sources.

The physical characteristics, for example color and morphology, of substrate-based security features such as fibers, planchettes, and threads can be microscopically examined

Figure 12 Counterfeit US currency showing no ultraviolet response of the security thread simulation.

Figure 13 Ultraviolet response of a printed watermark simulation on counterfeit US currency.

and compared to the genuine specimen. The location of these features can also be evaluated. While genuine fibers, planchettes, and threads are embedded in the substrate, counterfeit features can be simulated by printing or gluing them to the surface. More sophisticated counterfeits will have embedded features, but microscopic examination will reveal difference in the color, morphology, or composition of these counterfeit features when compared to genuine specimens.

Microscopic analysis will also reveal security features that may not have been successfully reproduced by the printing technique chosen by the counterfeiter. Microprinting, for example, is small text that cannot be reproduced by low-resolution digital technology such as scanners and will often

Figure 14 Genuine microprinting on US currency.

Figure 15 Counterfeit microprinting reproduction.

Figure 16 Counterfeit intaglio printing.

be illegible on counterfeits that use that technology to acquire an image. More recently, however, the resolution in affordable digital technology has increased to where some of these devices will successfully reproduce microprinting from the genuine image (Figures 14 and 15).

Microscopy is the best tool to determine the printing method used to produce the suspect counterfeit banknote. Different methods of printing have different characteristics that can be observed with magnification. The four printing processes used to produce genuine currency, intaglio, letterpress, offset, and screen, have been discussed but counterfeit versions of these printing processes can be used and will possess similar characteristics as their genuine counterparts (Figures 16–19). The following printing processes are also known to be used to produce counterfeits.

Halftone offset lithography

If a counterfeiter wants to use offset lithography to entirely produce their counterfeit image, they will sometimes use

Figure 17 Counterfeit letterpress (typography) printing.

Figure 20 Counterfeit halftone offset printing.

Figure 18 Counterfeit offset printing.

Figure 21 Counterfeit full color toner printing.

Figure 19 Counterfeit screen printing.

Figure 22 Counterfeit inkjet printing.

halftone offset because of its ability to produce tonal variations that regular offset lithography cannot. A screen or computer is used to break up the desired images into a series of dots that range in size and location and once combined together will create the illusion of a continuous tone. If full color separation is desired to simulate the various shades and colors of the genuine currency, a full color halftone process can be used in which the subtractive color mixture of cyan, yellow, magenta, and black (CMYK) are used in various combinations to create the illusion of the distinct colors contained in the genuine image (Figure 20).

Laser technology

Digital devices that use dry toner such as copy machines and laser printers will produce images composed of tiny plastic particles that have been fused to the surface of the substrate. Under magnification, the image will resemble melted plastic with stray toner particles scattered along the edge of the image area (Figure 21).

Inkjet technology

Inkjet-produced images are composed of ink dots that have absorbed into the paper. These dots will be flat and irregularly shaped. Legacy inkjet devices used basic CMYK components but newer devices have the ability to use a vast array of color options (Figure 22).

Bleached Currency Examinations

Paper currency substrates possess unique characteristics and a unique 'feel' that is often recognized as currency. Because of this, some counterfeiters want to use currency paper to produce their counterfeits. They will 'bleach' or chemically remove the ink from low-denomination banknotes leaving a blank piece of currency paper for use as a substrate for their counterfeit image. The image of a higher-denomination banknote is printed on the genuine currency paper, which will possess any

Figure 23 Bleached genuine \$5 printed as a counterfeit \$100 showing retained \$5 security thread and security watermark.

paper-based, embedded security features of the denomination that was bleached, making it a more deceptive counterfeit (Figure 23).

An examination of bleached counterfeits may reveal signs of the process. The process of bleaching involves not only the use of chemicals but also the abrasive process of removing the ink from the paper. A microscopic examination of a bleached counterfeit may reveal a disruption in the genuine paper fibers from this process as well as the removal of the paper's surface sizing. This will result in the topography and color of the bleached paper being distinguishable from original genuine paper. Residual images of the original banknote may also remain if the bleaching process was not completed correctly. Any postbleaching steps taken by the counterfeiter to improve the bleached paper's texture or printability can be detected microscopically.

Inkjet Examinations

Thin-layer chromatography is a common and rapid technique used to separate the organic components of inkjet inks and provide an easy side-by-side comparison of the dyes in the ink formulations. While a conclusion can be made that the inkjet chromatogram is consistent with a specific manufacturer of inkjet ink, it cannot be used to conclusively link a suspect inkjet printer to a suspect counterfeit banknote and should be supported by other investigative or forensic information.

Counterfeits will commonly use an all-in-one inkjet printer and use the scanning capability to obtain the image from a genuine banknote. When this procedure is used, any defects on the scanner glass or lid such as dirt or scratches can be detected in the printed sheets of counterfeits. These 'trashmarks' can help conclusively link a suspect inkjet printer to the counterfeit that was produced from that printer.

Chemical and Instrumental Examinations

Spectroscopy, elemental analysis, and chromatography of components such as the paper and ink of the suspect banknote may also be utilized to compare a suspect banknote to genuine and obtain valuable information that may benefit a counterfeit investigation. Research efforts have focused on characterizing specific inkjet inks using methods such as Raman spectroscopy. While these methods may not be necessary when simply determining if a suspect banknote is counterfeit, they could provide valuable investigative information when needed.

Summary

Paper currency is a method that has been used throughout history to purchase or trade goods and services. As long as paper currency has been used, the threat of counterfeiting has existed. Being able to recognize printing processes and security features used to produce genuine currency will assist an examiner in identifying a counterfeit as many methods used to produce counterfeit differ from the genuine methods.

Identity Theft

Z Geradts, Netherlands Forensic Institute, Den Haag, The Netherlands

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Identity fraud Mostly the same as identity theft.

Identity theft The crime of obtaining the personal or financial information of another person for the sole purpose of assuming that person's name or identity in order to get access, to make transactions or purchases.

Personal identifier A personal personal identifier is a data element within a data set that singly or in combination

can uniquely identify an individual, such as a social security number, name, address, birth date, physical characteristics, demographic information (e.g., combining gender, race, occupation, and location), and hospital-patient numbers (definition from IT law wiki).

Skimming Copying the magnetic stripe or contents of the chip of a banking or credit card.

Introduction

The term identity theft is often used for identity fraud or more generally, for identity-related crime. An example is a skimming case where the magnetic strip of a bank card is copied, as well as the pin code, and money is taken from a bank account without the owner of the account being aware of this. Other examples are creating profiles of person on social networks, which are not yet registered, or using stolen passports for opening bank accounts and making financial transactions.

Stealing someone's identity completely is not possible; most often data or information that represents an individual's identity is stolen. In understanding the nature of identity-related crimes, it is also useful to look at lawful and unlawful identity changes. Lawful identity changes are, for instance, writing under a pseudonym on social networks or publishing in books, which are common.

Often a person possesses a certain personal identifier. The personal personal identifier can be something a person knows, such as a password or pin code, or something a person owns, such as biometric features, for example, fingerprints or iris or a token that generates codes or an identity document. Sometimes they are used in combination.

Identity theft is defined in the US 1998 Federal Identity Theft and Assumption Deterrence Act as when an individual 'knowingly transfers or uses, without lawful authority, a means of identification of another person with the intent to commit, or to aid or abet, any unlawful activity.'

The literature, further differentiates identity-related crimes as

- identity collision: a wrong link is accidentally made between personal personal identifier and individual
- identity change: a wrong link is intentionally made between personal personal identifier and individual (the personal identifier may be a personal identifier to an existing individual or a newly created one)
- identity obstruction: a personal identifier is accidentally or intentionally erased
- identity restoration: a deleted personal identifier is restored by the individual and the linkability of the individual is reestablished

The phrase 'identity theft' is often used in the United States for banking frauds, where people use someone else's credit card or social security number for financial transactions. On the Internet, there are often weak systems for identity verification, such as password-only verification. The weakness of this system is that someone else also can use the service if they possess the password, which can be prevented by using a two-step verification, much like you see on a banking Web site, a password plus a code that is only used once.

In the United States, the number of incidents of personal identity theft number is around 9–10 million per year, or approximately 4% of the US adult population. Seven percent is related to medical identity fraud to claim on someone else's insurance. In the European Union, the number of cases of identity fraud is growing, for example, in the United Kingdom, there were 100 000 cases of identity fraud in 2007 (the rate of identity fraud is growing 10% a year). In some countries, it is easier to commit identity theft than in others with stronger personal identifiers. The more a certain personal identifier is used, the weaker it gets, since each time it is used, there is also a chance it is copied by someone.

There are different ways of illicitly retrieving passwords and other data from persons, such as

- false e-mails purporting to be from an individual's bank asking for personal data (fishing)
- guessing or using passwords from other services and testing them
- keyboard bugs in both hardware and software, where the software approach can be easily installed as malware
- use of insecure network systems such as unprotected Wi-Fi and e-mail accounts. These are a source of valuable information, such as photocopies of passports and sometime passwords of other accounts. Typically, these personal identifiers can be used elsewhere.
- hacking systems where credit card numbers and passwords are stored
- sniffing USB and other communication channels

The more common types of identity theft are financial identity theft, medical identity theft, business identity theft,

and illegal border entry. The direct and indirect costs of identity theft for financial institutions and society are growing.

Identity Related to Biometrics

The following biometric features can be used in passport documents (as described in the ICAO (International Civil Aviation Organization) standards on biometrics): signatures, face, iris, fingerprint, and body height.

In other biometric systems, for example, for access in computers, in fitness centers, or for entry into buildings, other biometric features used include, hand shape, vein patterns on hand, weight of a person, and handwriting characteristics.

Identity fraud at borders is possible by using a 'look a like,' since face comparison software in real-life situations has high error rates. Furthermore, people age, can use make up, and make other changes to their face, and the quality of image in the passport is limited due to storage on the radio-frequency identification (RFID) chip. Small and important details (such as scars and birthmarks) on the face may not be visible anymore.

If a fingerprint is stored, the fingerprint can be compared; however, in practice, often fingerprints are not very well acquired, and this gives error rates in the comparison. It is also possible to spoof fingerprints. However, by checking the person if the fingerprint has been spoofed and watching the person entering the biometric system, this can be prevented. Also, countries are aware of privacy concerns of their citizens and might not store this data anymore.

Spoofing an iris is more complicated if a proper life detection algorithm is used. In India, currently there is a project on storing both iris and fingerprint from all their citizens.

Also, other forms of biometrics are used in forensic science, but these are not used in biometric verification systems. DNA is too complicated, and of course, the collection of the DNA sample should also be watched carefully.

The increasing frequency of use in places such as fitness clubs means that they may be stored in low-security systems amenable to attack or abuse by others for identity theft. The drawback of using biometrics is that they cannot be easily revoked or changed if they have been compromised.

Virtual Identities

Since most identity verification is by unmanned digital systems, they become more sensitive to attacks. The person who likes to enter the system can take the time to investigate the system as such, do testing of the system itself, and find specifications on the design.

Virtual identities are not necessarily illegal since people often use nicknames at social networking and gaming software. However, if a crime is committed in the virtual world, for instance, by stealing someone's money in the virtual world in a game or social networking software, it becomes a virtual crime.

Since criminals will use many methods to conceal their real identity, it is difficult to investigate, and this kind of cybercrime often crosses international borders. Often, combinations of harvesting personal identifiers such as credit card numbers

with malware or cracking unsecure systems are carried out. Currently, malware developers are aware of virus and malware checking software, so they will try to circumvent the protection by changing the malware rapidly.

Forensic Properties of Verification and Identification Systems

The questions that have to be answered in an investigation include how reliable is the underlying technology? This depends on what kind of technology has been used, how secure is it, and is there any experience with the combination of technologies.

How well is the individual bound to the personal identifier? This is of interest in access control of buildings and RFID cards in public transportation, or as well in mobile phones. These devices and cards can be stolen from a person, and often, it takes some time before a person notices this.

Transparency

How well is it possible to audit if a biometric system actually does what it says? How transparent is the software, open source implementation can be verified easier than proprietary implementations, where it is not verifiable what actually happens in the device. If a manufacturer discloses the exact way the biometric system works, it becomes easier to check.

There might be a data retention law that applies for the system, and of course, there might be an ethical issue depending on a country's standards concerning storage of fingerprints. How long is data kept in the system?

Unintended Audit Trail

In software implementation, often for debugging purposes, interim results or data is stored in the system. However, in practice, it appears that it is not always deleted, which helps in investigations, but is unintended.

Examples of Identity Fraud (Skimming, Wrong Persons in Prisons, Banking Fraud, and Spoofing) and Relating them to Other Articles

A well-known method for identity fraud is skimming of credit and banking cards. The skimming device is often integrated in an automatic teller machine (ATM) or point of sale terminal by the perpetrator, during out-of-office hours. The copying of the magnetic stripe is easy with a magnetic swipe card reader.

There are several methods for integrating this device without the customers being aware of it. In the early days of this crime, customers were not aware of this kind of crime, so changes to the front of ATM or point of sale (POS) were not detected. For the skimming fraud, it is important to have a copy of the magnetic stripe and the pin code. The pin code can be acquired with a camera or by integrating it in the keypad. Later on, there were complete fronts being used, or the POS was revised that the customers are not aware of it.

Figure 1 Schematic overview of identity system.

Nowadays, skimmers often use good encryption to store the data from the skimmed device since otherwise, other perpetrators might steal it. Often the perpetrators will harvest the data for a longer time, of several days to weeks or months, and then collect the data, or they might also transfer the data wireless to their system.

The crime often gets detected later by the bank following by complaints of customers that money has been taken from their accounts. These kinds of crimes are often international since the money is taken abroad from the customers. Such crimes can also be detected by intelligent data analysis of the ATM traffic.

Most banks in the European Union have switched to chip cards. However, this is not the case elsewhere in the world, so the magnetic stripe will be there for several years, until this vanishes. However, the current standard of EMV (Eurocard, Mastercard, Visa) with the chip also has weaknesses, as is described by Murdoch et al.

For forensic investigation, it is important to collect the manipulated devices and carry out the customary DNA and fingerprint analysis. Also, by making databases of these devices, intelligence can be made from the methods used, and if perpetrators are caught, more cases by the same groups can be solved. The digital analysis of the skimming device is also important since the banking numbers should be found and customers can be informed. This is also an important evidence for court. The storage of the data from the camera can also be important as evidence since sometimes video is stored from the perpetrator themselves.

Other cases are with online banking accounts, where the account information is stolen and money is wired to other bank accounts, which is most often an international crime. The criminals later on try to find the so-called money mules by contacting them (much spam derives from this) and will ask to take the money from the account keeping a certain amount and send it further to an address. Investigation of this kind of crime is by studying the *modus operandi* of the crime and using intelligent data analysis algorithms at banks. They often result in complicated cases in forensic evidence since it is international and the perpetrators learn from earlier experiences of how to prevent from being caught.

Future Expectations

In future cases, it is expected that biometric features might become less trustworthy, especially if they are stored in systems that are not secure. Investigations of cloud systems, where all kinds of data are stored, can also be a challenge to track data leaks. The investigation of identity crime will require increasingly more resources for law enforcement, especially if criminals use strong encryption and hiding techniques. Identity theft if used on a large scale is related to cyber terrorism.

In **Figure 1**, the issues are visualized. With the user registration, it is important to have the right person, otherwise the wrong identity propagates through the whole system. The method of identity verification is important, as well as how well does it work and how many false rejects and false accepts does it have. Furthermore, the denied user can still enter the system if the person proves his/her identity. The denied person can use alternative identifiers, such as mother's maiden name, which might be weak.

Glossary

Alter Ego 'Second Self' under the doctrine of Alter Ego, the owners of the corporation are held responsible for the corporate acts, disregarding the corporate entity.

Answer The formal response by a defendant to a plaintiff's complaint.

Asset Anything tangible or intangible that is capable of being owned or controlled to produce value and that is held to have positive economic value is considered an asset.

Asset approach A general way of determining a value indication of a business, business ownership interest, or security using methods based on the value of the assets net of their liabilities.

Authentication The process of making a written document admissible as evidence.

Benefit of the bargain rule A rule permitting a defrauded purchaser to recover the differences between the actual value received and what the purchaser expected to receive.

Benford's law A law used by auditors to identify fictitious populations of numbers, and applies to any population of numbers derived from other numbers. This law also gives the expected distribution for digits beyond the first, which approach a uniform distribution as the digit place goes to the right.

Best evidence rule The rule requiring that the best evidence available (i.e., an original document or object) be presented unless it is shown that the original has been lost, destroyed, or not subject to the jurisdiction of the court.

Bid rigging A scheme in which a vendor is given an unfair advantage in an open competition for certain goods and/or services.

Bona fide In good faith; without fraud or deceit.

Business enterprise A commercial, industrial, service, or investment entity (or combination thereof) that pursues an economic activity.

Business risk The amount of uncertainty in realizing expected future returns of the business resulting from other factors than financial leverage (also see Financial Risk).

Business valuation The act or process of determining the value of a business enterprise or ownership interest.

Capital structure The makeup of the invested capital within a business enterprise; the mix of debt and equity financing.

Cash flow Cash that is generated over a period of time by an asset, group of assets, or business enterprise. It may be used generally to encompass various levels of specifically defined cash flows. Cash flow should be supplemented by a qualifier (for example, discretionary or operating) and a definition for a particular valuation context.

Cash 'T' A term used in conjunction with the reconstruction of income. It is an analysis of all of the cash received by the taxpayer and all of the cash spent by the taxpayer over a fixed

period of time. The theory of the Cash 'T' is that if a taxpayer's expenditure during a given year exceeds reported income, and the source of the funds for such expenditure is unexplained, such an excess amount represents unreported income.

Channel stuffing Various schemes that stuff the distribution channel with revenue that may be fraudulent (e.g., bill-and-hold schemes).

Circumstantial evidence Evidence from which the truth or validity of an issue may be proved indirectly.

Class action A lawsuit brought on behalf of a class of persons by one or more persons with claims that are typical of and fairly represent the claims.

Collateral estoppel The rule that a prior judgment in a case involving the same parties (or persons privy to those parties) bars retrial of issues decided in the prior judgment.

Common size statements Financial statements in which each line is expressed as a percentage of the total. On the balance sheet, each line item is shown as a percentage of total assets and, on the income statement, as a percentage of sales.

Compensatory damages Damages to recompense an injured party for an injury and restore the injured party to his or her original position prior to the injury.

Compliant The formal written pleading expressing a plaintiff's claim for relief and initiating a court action.

Computer forensics The procedures applied to computers and peripherals for gathering evidence that may be used in civil and/or criminal courts of law.

Consequential damages Damages that do not result directly and immediately from an act but instead result from the consequences of results of that act.

Correspondent banking A situation in which one bank provides services to another bank to move funds, exchange currencies, and access investment services such as money market accounts, overnight investments accounts, CDs, trading accounts, and computer software for making wire transfers and instant updates on account balances.

Cost approach A general means of determining an individual asset's value by quantifying the amount of money required to replace the future service capability of the asset.

Cost of capital The expected rate of return required by the market to attract funds for a particular investment.

Covenant A promise to do or not to do something.

Cross-examination - Questioning of a witness by the attorney for the opposing party.

Cybersmear The practice of sending out a large quantity of electronic messages to bash a stock in hopes of causing the stock price to decline.

Data mining A technique that uses mathematical algorithms to seek hidden patterns or associations in data.

Demonstrative evidence Objects of documents (photos, videos, models, charts, etc.) that illustrate points of testimony but possess no probative intrinsic value.

Demurrer A defendant's allegation that the issues alleged in a complaint are insufficient to require the defendant to respond to them.

Direct evidence Evidence that directly proves a fact at issue, without the need for any inference or presumption, usually based on personal knowledge of the witness.

Direct examination Question of a witness by the attorney for the party for whom the witness is testifying.

Discount rate A rate of return used to convert a future sum into its present monetary value.

Discounted cash flow method A method within the income approach in which the present value of future expected net cash flows is determined using a discount rate.

Discounted future earnings method A method within the income approach in which the present value of future expected economic benefits is determined using a discount rate.

Drill down functionality A feature of software that enables forensic accountants to go below the surface of a financial statement and uncover the source of any number and how it was calculated.

Embezzlement The fraudulent appropriation of money or property lawfully in one's possession to be used personally by the embezzler. An embezzler steals from his or her employer.

Employee fraud The use of fraudulent means to take money or other property from an employer, usually involving some kind of falsification (e.g., false documents, lying, exceeding authority, or violating employer policies).

Evidence The testimony, writings, and material objects offered in court to prove an alleged fact of proposition (also see Circumstantial Evidence, Demonstrative Evidence, and Direct Evidence).

Excess earnings The amount of anticipated economic benefits exceeding an appropriate rate of return on the value of a selected asset base (commonly, net tangible assets) used to create those anticipated economic benefits.

Excess earning method A specific way of determining a business valuation, business ownership interest, or security value, by summing the value of assets derived by capitalizing excess earning and the value of the selected asset base. The method also is frequently used in valuing intangible assets.

Expert report A written report prepared about a dispute by an expert witness.

Expert witness A person, who, because of specialized training or experience, testifies in court to enable the judge and/or jurors, to understand complicated and/or technical subjects.

Fact witness A witness who testifies as to facts.

Financial Crimes Enforcement Network (FinCEN) A bureau of the U.S. Department of the Treasury dedicated to enhance the integrity of financial systems by facilitating the detection and deterrence of financial crime. FinCEN receives and maintains financial transaction data; analyzing and disseminating that data for law enforcement purposes; and

building global cooperation with counterpart organizations in other countries and with international bodies.

Financial risk The degree of uncertainty of realizing expected future returns of the business resulting from financial leverage (also see Business Risk).

Foreign Corrupt Practices Act (FCPA) Prohibits corrupt payments to foreign officials for the purpose of obtaining or keeping business.

Forensic accounting The use of intelligence-gathering techniques and accounting/business skills to develop information and opinion for use by attorneys involved in civil litigation and/or criminal proceedings and give trial testimony if called upon; the action of identifying, recording, settling, extracting, sorting, reporting, and verifying past financial data or other accounting activities for settling current or prospective legal disputes or using such past financial data for projecting future financial data to settle legal disputes.

Goodwill The intangible asset created as a result of name, reputation, customer loyalty, location, product loyalty, and similar factors not separately identified.

Grand Jury A panel of 16–23 sworn individuals, that meets on a biweekly and/or monthly basis with the prosecutor to review evidence in order to authorize an indictment.

A Grand Jury has the power to accuse but not the power to convict.

Hearsay An out-of-court statement of another party offered during a court proceeding to prove the truth of the matter asserted.

High -low method An approach that identifies the highest and lowest costs, along with their related activity levels. The difference is calculated between the two costs and the two activity levels. The difference in costs is then divided by the difference in activity levels to determine an estimate of the variable cost per unit.

Income approach A general way of determining a business valuation, business ownership interest, security value, or worth of an intangible asset using one or more methods that convert anticipated economic benefits into a present amount.

Intangible assets Nonphysical property such as franchises, trademarks, patents copyrights, goodwill, equities, mineral rights, securities, or contracts that grant rights and privileges, and possess value for the owner.

Internal rate of return A discount rate at which the present value of the investment's future cash flows equals the cost of the investment.

Interrogation The process of questioning an individual suspected of being involved in a crime.

Interview The formal questioning of an individual.

Intrinsic value The value an investor considers, after evaluation or consideration of available facts, to be the true of real value that will become the market value when other investors reach the same conclusion.

Invested capital The sum of equity and debt in a business enterprise. Debt is typically all interest-bearing debt or long-term interest-bearing debt. The term should be supplemented by a specific definition in the given valuation context.

Invested capital net cash flows Those cash flows available to distribute to equity holders as dividends and debt investors as principal and interest after funding operations of the business enterprise and making necessary capital investments.

Investment value The value of an investment for a particular investor based on individual investment requirements and expectations.

Judicial precedent A court decision establishing a legal principle that subsequently is followed in cases having similar or identical facts.

Kiting Building up balances in bank accounts by floating worthless checks drawn against similar accounts in other banks.

Lapping The recording of payment on a customer's account some time after the receipt of the payment, so that cash is taken to be covered with the receipt from another customer.

Larceny of cash The theft of cash after the cash has been recorded on the books, such as directly from a cash register or petty cash.

Layering transactions The creation of a set of complex transfers to disguise the original source for the money and to hide and/or destroy the audit trail.

Liquidated damages clause A clause in a contract that specifies a dollar amount that a party will pay if that party breaches the contract.

Liquidation value The net amount that would be realized in a business terminates and its assets are sold piecemeal. Liquidation can be either orderly or forced.

Liquidity A property of an investment that enables it to be quickly converted to cash or payment to settle a liability.

Logs Manual and/or electronic records of the activities that have occurred.

Manipulation The falsification or alteration of accounting records or supporting documents from which financial statements are prepared.

Market approach A general way of determining a business valuation, value of a business ownership interest, security price, or intangible asset's value by using one or more methods that compare the asset to similar businesses, business ownership interests, securities, or intangible assets that have been sold.

Marketability The capacity to quickly convert property to cash at minimal cost.

Materiality The measure of whether something is significant enough to change an investor's investment decision.

Minority discount A discount for lack of control applied to the value of a minority interest.

Minority interest A business ownership interest of less than 50% of the voting interest.

Misappropriation The act of obtaining something of value or avoiding an obligation by deception.

Misrepresentation The intentional omission from the financial statements of events, transactions, or other significant information.

Money laundering The use of techniques to take money coming from one source, hide that source, and make the funds available in another setting so that the funds can be used without incurring legal restrictions or penalties.

Motion A request to a court for a rule or order in the applicant's favor.

Motion in limine A pretrial motion requesting a court to prohibit opposing counsel from offering certain evidence.

Net book value The difference between total assets (net of accumulated depreciation, depletion, and amortization) and total liabilities as they appear on the balance sheet of a business enterprise.

Net fraud A scheme to ensnare unsuspecting internet users into giving up their resources to an online criminal.

Net present value The value of the tangible assets of a business enterprise (excluding excess assets and nonoperating assets) minus the value of its liabilities.

Nonoperating assets Assets unnecessary to the ongoing operations of a business enterprise.

Opinion report A report by an expert, such as a valuation report, that is more subjective and relies more on the professional judgment of the expert than does a fact-oriented report.

Out-of-pocket loss Damages measured as the difference between the actual value received and the actual value conveyed.

Parol evidence Oral evidence.

Payable through account A bank account enabling the respondent bank's clients within the country where the bank is registered to write checks that are drawn directly on the respondent bank's correspondent account in the United States.

Pleadings The formal written allegations of the parties in a lawsuit which includes the complaint and answer, each expressing their respective claims and defenses.

Present value The value as of a specified date, of future economic benefits and/or proceeds from sale, determined using an applicable discount rate.

Privileged communications Statements made between individuals within certain protected relationships such as attorney and client and priest and penitent.

Pump-n-dump A trading scheme causing thinly traded stock to move up rapidly in price after which the perpetrator sells the stock at a huge gain.

Punitive damages Damages awarded in excess of actual damages sustained in order to punish reprehensible conduct and deter future wrongdoers.

Qui tam action A lawsuit filed by a whistle-blower under the Federal False Claims Act against a company or contractor on behalf of the Federal Government.

Rate of return An amount of an investment's income or change in value, either realized or anticipated expressed as a percentage of that investment.

Redirect examination Testimony in which the direct examiner gives the witness the opportunity to clear up any confusion that may have been caused by the cross-examination and complete any answer that the witness could not complete during cross-examination.

Rejoinder A defendant's pleading in answer to a plaintiff's reply.

Reply A plaintiff's pleading that is required or permitted to respond to a defendant's setoff or counterclaim.

Residual value The value at the conclusion of the discrete projection period in a discounted future earnings model.

Res judicata The rule that a final judgment by a court of competent jurisdiction on the merits of a case is conclusive as to the rights and facts at issue that bars and subsequent action involving the same cause of action brought by the same parties.

Respondent The person against whom an appeal is made to a higher court.

Return on equity A percentage amount earned on a company's common equity for a given period.

RICO laws Racketeer Influenced and Corrupt Organization Laws are a set of laws specifically designed to target illegal acts by organized crime groups.

Rules of evidence The rules governing the admissibility of evidence and the weight that evidence is given.

Scienter The guilty knowledge of the defendant.

Skimming An off-book technique to remove cash before it is properly recorded.

Smurfing A money laundering technique in which individuals working for the money launderer deposit random amounts of cash less than \$10 000 into numerous named accounts at various financial institutions to evade and/or avoid reporting requirements.

Sniffer A program used to secretly capture data moving across a computer network and to disclose and analyze these data packets.

Source and application of funds method Also called the 'expenditure method', this is a technique approved for use by the Internal Revenue Service that shows increases and decreases in a taxpayer's accounts for a given period.

Subpoena A command presented to a witness to appear at a specified time and place in order to testify.

Subpoena duces tecum A command to produce specified documents or other items to the court.

Summary judgment A judge's disposition of a controversy without a trial when there is no dispute about a material fact and the case involves only a question of law.

Surrebutter A plaintiff's reply to a defendant's rebutter.

Surrejoinder The plaintiff's response to a defendant's rejoinder.

Tangible assets Physical assets such as cash, accounts receivable, inventory, property, plant, and equipment.

Tort A civil wrong or wrongful act, whether intentional or accidental, from which injury occurs to another.

Trier of fact A court, regulatory body, or government agency, a grand jury, or an arbitrator or mediator of a dispute.

Trust A legal relationship that is established by one person when assets have been placed under the control of another person for the benefit of the beneficiary for a specific purpose.

Valuation The process of determining the worth of a business, business ownership interest, security, or intangible asset.

Valuation approach A general way of calculating a value indication of a business, business ownership interest, security, or intangible asset that uses one or more valuation methods.

Valuation date The specific point in time as of which the valuator's report of value applies.

Vertical analysis The approach, often referred to as common-size statements, that presents every item in a statement as a percentage of the largest item in the statement.

Voir dire examination The preliminary questioning by an attorney (or court) of juror candidates to determine whether they are qualified to serve as a juror.

Washing checks The process of chemically removing the original payee and the amount from a check in order to substitute another payee or amount.

Work product rule Rule that protects personal memoranda, written statements of witnesses, and other materials prepared by an attorney in anticipation of litigation from disclosure to other parties involved in litigation. The work product rule was developed to prevent an attorney's work from being used against a client and undermining the attorney-client privilege.

Writ of certiorari An appellate court's order requiring a lower court to certify the record and send it for review by the higher court.

Writ of elegit An order to seize a portion of a debtor's lands and all his/her goods (except work animals) toward satisfying a creditor, until the debt is paid off.

Writ of fieri facias An order directing the sheriff to take and auction off enough property from a losing party to pay the debt (plus interest and costs) owed by a judgment debtor.

Writ of replevin A court order to regain personal property held or retained by another. It usually involves the process that a bank or lending institution take to recover collateral (cars, trucks, mobile homes, boats, campers, furniture, etc.).

Zipf's law A natural phenomena in which the frequency of any word is inversely proportional to its rank in the frequency table. Thus, the most frequent word will occur approximately twice as often as the second most frequent word, three times as often as the third most frequent word.

Introduction

With all of the recent corporate accounting scandals at Parmalat, Xerox Corporation, and Satyam Computer Services, and all the high-profile corporate frauds at Enron, World Com, and Health-South followed by Bernie Madoff's colossal ponzi scheme, the media has made forensic accounting into a growing industry.

While all the recent media attention given to forensic accounting may give one the impression that this is something

new, in reality, the practice of forensic accounting has been around since the sixteenth century. Court records from Antwerp, Belgium, show in 1554 Hercules DeCordes, a 'bookkeeper,' was recognized as an expert witness when he testified about the accounting records he maintained.

In 1946, Maurice Peloubet, a New York CPA, was the first person to coin the phrase 'forensic accountant.' For it is the Forensic Accountant that is tasked with the daunting responsibility of reconstructing the complex financial puzzle

after the discovery of fraud, embezzlement, or elaborate ponzi scheme. It is the forensic accountant's mission to rebuild the entire financial system to uncover the fraud scheme(s) employed. This is accomplished by painstakingly reviewing financial transactions such as inventory records, payroll disbursements, canceled checks, bank and credit card account records, wire transfers, cashier check purchases, expense reports, and nonfinancial information such as e-mails, text messages, phone logs, purchase orders, vendor files, personnel records, and passport activity.

In most situations, the forensic accountant will appear in court to present his or her work; therefore, the forensic accountant must have knowledge pertaining to the rules of evidence for courtroom proceedings and must demonstrate that due professional care and proper chain of custody was maintained for all paper and electronic evidence entrusted to him. On completion of the forensic accounting engagement, the forensic accountant must be able to present his or her findings in a written report that is clear, concise, and presents the facts in a persuasive manner.

In short, it is the forensic accountant's role to determine what happened, explain how it occurred, and offer a fair and reasonable evaluation for computation of damages. In some cases, the Forensic Accountant may be called upon to develop a series of recommendations to prevent and deter future losses.

Forensic Accounting for Criminal Investigations

Today, local, state, and federal law enforcement agencies seek the use of forensic accountants to investigate financial crimes such as

- arson for profit,
- bank fraud,
- embezzlement,
- health care fraud,
- insurance fraud,
- money laundering,
- mortgage fraud,
- organized crime business enterprises,
- ponzi schemes,
- securities and commodities fraud,
- tax evasion, and
- terrorist financial networks.

The father of forensic accounting for law enforcement was none other than Mr. Frank Wilson.

Frank Wilson was a certified public accountant working for the Internal Revenue Service when, in 1930, he was assigned to a Federal task force investigating the notorious Chicago gangster, Al Capone.

In searching records, Wilson found an accountant's cash receipts ledger showing net profits from gambling, with Al Capone's name on it.

It was this single document that allowed Wilson to prove that Al Capone had indeed earned 'illegal income,' which he had failed to report, that was subject to federal income taxation.

Although there had been many attempts to convict Capone for various other illegal activities, he was never found guilty. In fact, he thought Wilson's investigation and the tax evasion charges were a joke.

In response to these charges he stated the following:

"The income tax law is a lot of bunk. The government cannot collect legal taxes from illegal money."

In 1931, on the strength of the forensic accounting analysis of Capone's personal and business accounting records by Wilson, Al Capone was indicted for federal income tax evasion for the years 1925–29, in addition to the failure to file tax returns for the years 1928 and 1929.

Wilson's detailed forensic accounting methods determined that Capone owed \$215 080.48 in federal income taxes from his 'illegal gambling profits'.

Capone was found guilty of tax evasion and Judge Wilkerson sentenced him to 10 years in Federal Prison and 1 year in the county jail.

Wilson's work on the Capone investigation set the foundation for modern-day forensic accounting and financial investigation applications in law enforcement.

It was Frank Wilson, CPA, who was able to prove to the world that it takes a forensic accountant to catch a crook!

Forensic Accounting Tools

In order to analyze the subject's financial transactions, the forensic accountant may have to search for it. When facing these circumstances, the forensic accountant should begin his or her search with public record databases. Government entities in cities, counties, and states compile a wealth of information on both individuals and corporations.

On state web sites, the forensic accountant will find a vast array of information on every corporation registered with the state, including the names of the officers and registered agents for corporations, limited liability companies, limited partnerships, and general partnerships in addition to fictitious name registrations and lien filings are readily available online.

The City or County Property Appraiser has important information pertaining to the ownership and transaction history for every parcel of real and taxable personal property in the county. Additional real estate information is also available from a service called *Zillow*, which provides free real estate information about homes for sale, home prices, home values, and recently sold homes for any location in the United States.

All records pertaining to every legal proceeding are presented in court dockets, which are maintained by the office commonly referred to as the Clerk of the Court. The Clerk of the Court's web site can provide the details and copies of actual documents related to the court proceedings for the following: arrest and conviction records, traffic citations, affidavits and motions filed by plaintiffs and/or defendants, marriage licenses, divorce decrees, final rulings, disposition of property, and a host of other court-related documents related to the assessment and payment of fines, fees, and court costs.

Every city and/or county has an official records custodian. The information contained on the records custodian's web site will provide the forensic accountant with the details for every 'recorded document,' such as deeds, declarations of domicile, foreign judgments, domestic partnership registration, liens, evictions, foreclosures, writs of replevin, writs of elegit, and writs of fieri facias.

Forensic accountants who are also members of the law enforcement community have access to a number of specialized investigative Web sites and databases.

The first of these systems is maintained by the Federal Bureau of Investigation (FBI), and it contains a comprehensive database of criminal justice information in a computerized system known as the National Crime Information Center, more commonly referred to as NCIC. The information in NCIC may assist the forensic accountant in locating and returning stolen property.

The second system, known as the Financial Crimes Enforcement Network (FinCEN), was developed by the United States Department of the Treasury. FinCEN's mission is to enhance the US national security, deter and detect criminal activity, and safeguard financial systems from abuse by promoting transparency in the United States and international financial systems. FinCEN can provide forensic accountants with a variety of financial information pertaining to an individual and/or a corporation, such as the location of bank and stockbroker accounts, details of wire transfers, cash transactions, and suspicious activity involving financial institutions, casinos, insurance brokers, security dealers, check-cashing stores, foreign currency dealers, jewelers, and precious metal brokers.

It is important to note that any information the forensic accountant obtains from FinCEN is considered to be protected information as defined by the 'safe harbor' provisions of the Bank Secrecy Act. As protected information, any documents provided by financial institutions to FinCEN are not subject to discovery and cannot be disclosed to a third party or used as exhibits during trial. This advisory is provided to inform financial institutions of the recent court decision concerning the 'safe harbor' provision of the Bank Secrecy Act as applied to reports of suspicious transactions.

It is extremely important for the forensic accountant to organize and catalog all material received during the course of the financial investigation. In an effort to facilitate the collection and classification of data, a Background Investigation Checklist is provided in [Exhibit 1](#) and a Financial Investigation Checklist is provided in [Exhibit 2](#).

Surveillance and Investigation Tools

Pen registers and mail covers are two surveillance and investigation tools commonly used by law enforcement agencies that are extremely useful to the forensic accountant.

A pen register is an electronic device that records all numbers dialed from and to a particular telephone line. The term has come to include any device or program that performs similar functions to an original pen register, including programs monitoring Internet communications. Information obtained from a pen register can provide the forensic accountant with knowledge of foreign bank accounts and key data that can be used to produce a genogram.

A genogram is a pictorial display using symbols and lines to illustrate a person's relationships with other individuals. These graphic displays can be used by the forensic accountant at trial to help the judge and jury understand the intricate workings of a complex money laundering or fraud scheme.

"A mail cover is a law enforcement investigative technique that captures any data appearing on the outside cover of sealed or unsealed class of mail, or by which a record is made of the contents of any unsealed mail. Mail covers are allowed by law to:

1. obtain information to protect national security;
2. locate a fugitive;

3. obtain evidence of the commission or attempted commission of a crime;
4. obtain evidence of a violation or attempted violation of a postal statute; or
5. assist in the identification of property, proceeds, or assets forfeitable under law."

A mail cover does not involve the reading of the mail but only information on the outside of the envelope or package that could be read by anyone seeing the item anyway. Mail covers can provide the forensic accountant with vital information pertaining to income from unknown sources as well as an individual's lifestyle and spending habits. An example of a mail cover is presented in [Exhibit 3](#).

Forensic Accounting for Civil Litigation

With all the media attention pertaining to the practice of forensic accounting related to sensational fraud examination cases or ponzi schemes, it is easy to overlook the important role that forensic accountants play in examining and analyzing financial transactions for civil litigation matters such as

- divorce,
- bankruptcy,
- lost profit computations, and
- personal injury,
- wrongful death, and
- business interruption claims
 - mergers and acquisitions
 - gift and estate tax valuations
 - life care plans
 - buy-sell agreements
 - qui-tam actions.

The forensic accountant's role in the majority of civil litigation matters is to determine the economic value of damages an injured party has suffered. All things being equal, the injured party would like the damage calculation to be as large as possible, whereas the defendant would like the damages to be as small as possible.

In these cases, the basic assumption for the computation of damages is determined under the principle that compensation should place the injured party in the same position economically that they had before the harmful event took place. Because the computation of damages is based on the premise of 'what if nothing had occurred,' the forensic accountant engaged by the injured party will employ a series of assumptions and valuation methods to arrive at the highest possible damage estimate. Conversely, the forensic accountant representing the defense must find the means to form a creditable challenge to these assumptions in a professional manner to persuade the judge and/or jury to accept the much lower level of damages presented by the forensic accountant for the defendant.

When an injured party suffers an economic loss and seeks to recover damages, the forensic accountant needs to prepare a 'study of losses.' In accordance with the established legal framework, the 'study of losses' will include the quantification of the reduction in earnings/revenue, the calculation of interest

on past losses, and the application of financial discounting to future losses. In computing damages, the forensic accountant must also take into consideration that the injured party has a duty to take the necessary steps to mitigate or reduce the damages.

The standard formula for the computation of damages developed by the Federal Judicial Center's *Reference Manual on Scientific Evidence* is presented in the following table:

The key element in determining economic value of the damages is the measurement of the loss. Losses must be measured over the time period in which the injured party can recover from the wrongful harm; therefore, the forensic accountant must first define the loss period in order to begin the loss measurement process. The measurement process is commonly defined by one of three generally accepted methods: the closed period loss, the open period loss, and the infinite period loss.

In the closed period loss, the injured party over time has been able to recover completely and has realized a position that he or she would have obtained if the loss had never occurred. The closed period loss is illustrated in [Figure 1](#).

In the open period loss scenario, the injured party has been able to realize a partial recovery; however, the damages are so strong that the party will never realize the position he or she was in before suffering the loss. The open period loss is illustrated in [Figure 2](#).

Exhibit 3 Damage Calculation Formula

In the infinite period loss situation, the loss is so devastating that the injured party is never able to recover. The infinite period loss is illustrated in [Figure 3](#).

Forensic Accounting to Discover Hidden Assets

In divorce, bankruptcy, and partnership liquidation cases, it is not uncommon for one of the parties involved to employ elaborate means to deliberately conceal assets. In these cases where there is a suspicion that assets are disappearing or the asset values seem to be artificially too low, the forensic accountant is called in to verify valuations and locate and recover any hidden assets.

Figure 1 Closed period loss damage analysis.

Figure 2 Open period loss damage analysis.

Figure 3 Infinite period loss damage analysis.

There are two techniques that can be used to perform a forensic analysis to reconstruct unreported income: the direct method and the indirect method.

The direct method mirrors the steps of a traditional audit by examining

- financial statements,
- general ledgers,
- bank accounts,
- sales invoices, and
- canceled checks.

The direct method has one major drawback. In order to complete a direct method analysis, it involves the cooperation of the individual and/or organization under investigation to provide the forensic accountant access to the financial information.

On the other hand, the indirect method utilizes an array of covert means such as subpoenas, currency transaction reports, suspicious activity reports, social security wage reports, phone taps, trash pulls, mail covers, real property records, corporate officer records, occupational license filings, driver license records, vehicle registrations, and the testimony of confidential informant(s).

Of the two methods, the indirect method is the most commonly used to reconstruct historical financial results to identify income from unknown sources.

The indirect method for reconstructing income actually encompasses four distinct methodologies:

- cash T method,
- expenditure method (sometimes called source and application of funds method),
- bank deposit method, and
- net worth method.

The cash T method is the simplest indirect method to determine income from unknown sources. The forensic accountant simply compares all cash received to all cash spent. If cash spent exceeds cash received from known sources then excess may represent income from unknown sources.

The expenditure method is a three-step technique that scrutinizes the suspect's financial transactions throughout the year.

- Step 1 List all of the suspect's expenditures.
- Step 2 Subtract all the known sources of funds, including all cash on hand at the beginning of the year.
- Step 3 Analyze the difference to determine if the suspect has income from unknown sources.

The major advantage of the expenditure method is it is easy for people, especially for judges and jurors to understand.

The bank deposit method is a six-step method that is used when income is deposited in bank accounts and most of the expenses are paid by check. This method was approved by the courts almost 70 years ago. This income reconstruction technique has survived a multitude of legal challenges and has been used successfully to solve numerous financial crimes.

- Step 1 – Determine Net Deposits to All Bank Accounts
 - Add: Deposits to All Business, Personal, and Children Bank Accounts
 - Less: Transfers, Redeposits, Transfer of Funds and Checks Made Payable to 'CASH'
 - Equals: Net Deposits to All Accounts
- Step 2 – Determine Total Outlays Add:
 - All Business Expenses Paid by Either Cash or Check
 - Add: All Personal Expenses Paid by Either Cash or Check

Less: Depreciation, Depletion, and Bad Debts
 Equals: Total Outlays

Step 3 – Determine Net Bank Account Disbursements Net
 Deposits in All Bank Accounts
 Plus: Beginning Balance All Accounts
 Less: Ending Balance All Accounts
 Equals: Net Bank Account Disbursements

Step 4 – Determine Cash Disbursements Total Outlays
 Less: Net Bank Disbursements
 Equals: Cash Disbursements

Step 5 – Determine Total Receipts Net Bank Disbursements
 Plus: Cash Disbursements
 Equals: Total Receipts

Step 6 – Identify Funds from Unknown Sources Total Outlays
 Less: Net Bank Disbursements
 Equals: Cash Disbursements
 Plus: Net Deposits to All Accounts
 Equals: Total Receipts
 Less: Income from Known Sources
 Equals: Income from Unknown Sources

The net worth method is a five-step process that uses the changes in balance sheet items to estimate income.

To use this method of income reconstruction, the forensic accountant must calculate the suspect's net worth at both the beginning and end for each period under investigation. The goal is to identify differences between, income from known sources and increases in net worth for each time period under investigation.

In 1954, the US Supreme Court ruled in the tax evasion case of M.L. Holland that the Internal Revenue Service's use of the Net Worth Method to identify hidden income was sound. Since that ruling was issued in 1954, the Courts have permitted the Internal Revenue Service to make an inference that the taxpayer's income was underreported when the net worth (after the necessary adjustments had been made) increase was greater than the reported taxable income.

Step 1 – Calculate the Suspect's Net Worth (Current Year)
 Known Assets
 Less: Known Liabilities
 Equals: Net Worth

Step 2 – Calculate the Suspect's Net Worth (Prior Year) Known
 Assets
 Less: Known Liabilities

Equals: Net Worth

Step 3 – Calculate Year to Year Change in Net Worth Net
 Worth Current Year
 Less: Net Worth Prior Year
 Equals: Change in Net Worth

Step 4 – Determine Total Outlay of Funds Change in Net
 Worth
 Add: Known/Nondeductible Living Expenses and
 Capital Losses
 Equals: Total Outlay of Funds

Step 5 – Determine Income from Unknown Sources Total
 Outlay of Funds
 Less: Income from Known Sources
 Equals: Income from Unknown Sources

Conclusion

The culmination of the forensic accountant's work takes place when he or she enters the courtroom and takes the stand as an expert witness. The forensic accountant, in his or her expert witness testimony, must be able to explain complex financial transactions related to specified unlawful acts, or the computation and valuation of damages stemming from civil litigation in a manner that is understandable to the judge and members of the jury.

Glossary

Bank identification number (BIN) The first six digits of each payment card account number that numerically identify the issuing bank.

Card not present (CnP) transactions Transactions in which the physical payment card is not present.

Network-branded payment cards Payment cards that bear the logos of and function on the credit networks run by Visa, MasterCard, American Express, and Discover.

Payment cards A group of closely related financial products commonly known as credit cards, debit cards, and prepaid cards.

Payment Cards and Criminal Activity

Payment cards are often targets of fraud schemes, which are a type of white collar crime. The victims of payment card fraud are primarily the banks that issue the cards, as these financial institutions typically absorb fraud losses on behalf of their customers (the cardholders). While individual cardholders are also victimized by this activity, the cardholders' losses are typically far lower than the losses suffered by affected financial institutions.

What Are Payment Cards?

The term payment cards refers to a group of closely related financial products commonly known as credit cards, debit cards, and prepaid cards. In this article, only network-branded payment cards – that is, those cards which bear the logos of and function on the credit networks run by Visa, MasterCard, American Express, and Discover – will be discussed. Other payment cards (such as store credit cards, store gift cards, transit cards, and cards that run exclusively on debit networks) will not be discussed, as they are less commonly used in fraud, money laundering, and terrorist financing schemes.

- Credit cards: These payment cards follow a 'pay later' business model and allow cardholders to access a line of credit at point-of-sale locations. The financial obligations incurred during credit card transactions must be repaid, with varying rates of interest, as per the issuing bank's cardholder agreement. Each credit card is branded by and functions on a credit network.
- Debit cards: These payment cards allow customers to 'pay now' for point-of-sale purchases by drawing funds directly from the cardholder's checking or savings account. Most debit cards are branded by and run on a credit network, but can also be branded by and run on one or more debit networks. Because debit cards were originally used almost exclusively at automated teller machines (ATMs) that functioned on the money access card (MAC) debit network, the cards are frequently called ATM or MAC cards.
- Prepaid cards: These payment cards follow a 'pay before' business model by drawing value from funds provided to

the prepaid card program or a designee in advance of the cardholder's purchases. Prepaid cards are ideal for unbanked or underbanked financial services customers who do not have or do not qualify for credit or debit cards, but nonetheless require access to payment cards in order to make online purchases, reserve and pay for hotel stays, and rent cars. The prepaid cards discussed in this article are branded by and run on a credit network, but can also be branded by and run on one or more debit networks. Prepaid cards are sometimes called stored value cards, and are often incorrectly called prepaid credit cards or prepaid debit cards.

Network-branded payment cards have a specific visual appearance. Each card must bear the network brand (Visa, MasterCard, American Express, or Discover), which typically appears on the front of the card in the lower right-hand corner. On debit and prepaid cards issued in the United States, the word 'DEBIT' must appear above the network brand. Payment cards must also identify and contain contact information for the issuing bank. (Visa and MasterCard cards are issued by a wide variety of financial institutions, American Express is issued by a select group of banks including American Express, and Discover cards are issued only by Discover.) Debit and prepaid cards that also function on debit networks carry the logos of the relevant debit networks on the back of the card. Each card also bears one or more holograms and a signature block for the cardholder's signature. Data are encoded on a magnetic stripe (found on the back of the card), a chip (visible on the front of the card), or both.

Payment cards provide access to payment card account information in digital and analog formats. Payment cards issued in the United States and Canada are typically magnetic stripe cards. These cards use a magnetic stripe, located lengthwise across the back of the card, to electronically store account information. The stripe contains the account number, the name of the authorized user, and the card's expiration date, as well as discretionary data, separators, and other computer characters. Payment cards issued in Europe, Australia, and some parts of Canada are typically smart cards. Smart cards use an EMV-compliant (for Europay, MasterCard, and Visa) chip embedded in the card to store account data and provide an additional layer of security. These cards, which are commonly known as chip-and-PIN (personal identification

number) cards, require the cardholder to enter a four-digit PIN at point of sale. The PIN is verified by the chip, and is considered to be more secure than signature-based verifications, which can be easily forged and are often not verified at point of sale. Analog account information is stored on the front of each card in the form of raised letters that identify the authorized user, the account number, and the card's expiration date. Magnetic stripe cards also display a card verification value (CVV) number, the location of which varies by credit network, which is used for additional security during certain types of transactions. A more detailed physical description of magnetic stripe payment cards will be provided later in this article.

It is not necessary to possess the physical payment card to access the value associated with the card. The physical cards are merely vehicles that allow merchants to efficiently access the account information necessary to process transactions; all that is needed to access the value associated with a payment card is the account information. When a payment card is present at a point-of-sale transaction, the card's magnetic stripe or EMV chip is typically read by hardware designed for this purpose. The transaction is not completed until the account information travels through the appropriate credit network and an authorization – stating that the cardholder has enough value associated with the card to cover the transaction – is obtained. In a transaction involving an EMV card, the user's PIN (or security number) must also be provided and verified. In some cases, merchants may conduct transactions using devices that allow them to capture an imprint of the card's raised letters on carbon paper. In these situations, authorization is typically acquired after the act of the transaction. This method is often used if any of the infrastructures required to communicate with the credit network is unavailable. Transactions in which the physical payment card is not present are aptly known as card not present (CnP) transactions. These transactions, which typically occur online or telephonically, take place without reading or imprinting the payment card used. Depending on the level of security in these transactions, they may require as little information as the cardholder's name, the account number, the name of the credit network, and the card expiration date, all of which are visually available on the card. Many of these transactions also require the card's CVV number, which is also visually available on the card.

Network branded payment cards share certain physical characteristics. Knowledge of these characteristics may be helpful to a document examiner. A discussion of pertinent physical characteristics follows.

Plastic

A payment card is a sandwich of plastic – specifically, polyvinyl chloride (PVC) – and is die cut from a larger sheet. The white core plastic contains the printed material, program and issuer names, logos, ownership information on the back of the card, etc., which is covered by an overlay for protection. Depending upon the card manufacturer, the core may be a solid sheet of white PVC or two thin sheets of sandwiched white PVC. Not all PVC is the same. For example, two PVC plastic manufacturers may use the same compounds in their plastic, but the printability characteristics and whiteness can be different.

Overlay

The core is protected and sealed by a translucent overlay, the composition of which can vary among card programs. The ultraviolet (UV) characteristics of the overlay are critical because of UV fluorescent ink images printed on the core. The overlay must allow the UV light to pass through it and react with the UV-printed ink image so it will fluoresce.

Size

The nominal size of the card is 3.370 inch (85.60 mm) wide, 2.125 inch (53.98 mm) in height, 0.030 ± 0.003 inch (0.76 ± 0.076 mm) thick, and the corners are rounded with a radius of 0.125 ± 0.012 inch (3.175 ± 0.305 mm). Typically, the core is 0.027 inch (0.686 mm) thick and the thickness of each overlay sheet is 0.0015 inch (0.0381 mm). This size card is described as an ID-1 card by International Standards Organization (ISO) Standard 7810.

Ink

Both offset and screen printing techniques and inks are used to print cards. UV curing inks or drying agents are added to the ink to expedite the drying process. A color shift occurs in the ink during lamination.

Signature Panel

The signature panel appears on the back of the card. The signature panels are as varied as the card programs and issuers. Some are plain, offering little or no security; others are sensitive to solvents, or have complex printed backgrounds or other high-security features. The panel may contain the account number indent printed within it. The signature panel is attached to the individual card after it is die cut from the sheet.

The signature panel may be one of the following:

- a preprinted hot stamp panel attached to the card;
- several layers of screen-printed ink applied to the card, consisting of a base layer with printed information over it identifying the card program;
- special paper or printed material and inks sensitive to solvents that will react with the stripe if an attempt is made to alter the written signature; and
- a high-security printed panel with a variety of printing traps to prevent duplication by using a scanner.

Magnetic Stripe

The magnetic stripe is applied to the card as part of the lamination process, and may contain two or three tracks of information. If the stripe width is approximately 7/16 inch (11.11 mm), three tracks of information can be encoded, and if the stripe width is approximately 5/16 inch (7.94 mm), two tracks of information can be encoded.

Encoding consists of a series of zeros and ones, a binary format, where each number, letter, or character is a unique combination of '0' and '1.' ISO Standard 7811-2 and 7811-4 establish the number of bits per character. The standard also

requires an odd parity for each character bit set, regardless of the character. Odd parity is achieved by adding a 1 or 0 to a bit set, insuring it has more ones than zeros. Other technologies, such as watermark, magnetic, etc., are beyond the scope of this article.

The following is a brief description of the characteristics of a magnetic stripe data format based on ISO standards.

Track 1

This is known as the International Air Transportation Association (IATA) track. The character configuration is seven bits per character, including the parity bit, and the maximum information content is 79 alphanumeric characters, which includes the start sentinel, end sentinel, and longitudinal redundancy check character (LRC) at a recording density of 210 bits/25.4 mm per inch. The card magnetic stripe data format for track 1 is illustrated in [Figure 1](#) and described below. The encoded information is subdivided into fields read from right to left, as if the reader were looking at the back of the card.

- *A: Starting clocking bits.* Before data are encoded, a string of clocking bits is encoded and each bit equals zero. Clocking bits provide a timing mechanism for starting the reader synchronization process before the reader head gets to the start sentinel.
- *B: Start sentinel.* The start sentinel (%) is a defined number of bits informing the magnetic stripe reader that the following encoded information will be data.
- *C: Format code.* The format code consists of two digits telling the magnetic stripe reader how to interpret the data encoded in the data field. ISO established a standard of F2F (frequency-double frequency) for payment card magnetic stripes.
- *D: Primary account number (PAN).* The PAN field is the first data field read by the magnetic stripe reader and can have a maximum of 19 digits. The card program and issuer establish the PAN and its format in the data field. The format of the PAN is not the same in this field for all tracks on all payment cards.
- *E: Field separator.* Following the PAN is a field separator ({). Its purpose is to notify the magnetic stripe reader that all encoded data called for in the preceding field are encoded and a different information field is about to begin. On track 1, it signals the end of a numeric data field, the PAN, and the beginning of an alpha data field, the name of the card owner. On tracks 2 and 3, it signals the end of the PAN and the beginning of the next, numeric data field. The PAN field has frequently fewer than the allotted 19 digits. If the encoded number is 16 digits, the issuer or program may still require the use of the full 19-digit field by leaving the unused digits blank.
- *F: Cardholder name.* The next field on track 1 is the cardholder name, and its allotted size is a maximum of 26 alpha characters. How much of this field is used and the order in which the name is encoded (last name first, first name

K	J	I	H	G	F	E	D	C	B	A
---	---	---	---	---	---	---	---	---	---	---

Figure 1 The IATA track or track 1.

second, initials third, etc.) are established by the card program and/or issuer.

- *G: Field separator.* A field separator follows the card owner's name. Its function is the same as described in 'E' above.
- *H: Additional data and discretionary data field.* The next field is a numeric field containing encoded information, the expiration date, service code, pin offset, 'CVV,' etc. Each card program and/or issuer can dictate the information encoded in this field. The ISO Standard establishes the number of characters allotted to each specific entry; for example: the expiration date, four digits; the restriction or type, three digits; the pin offset or parameter – optional – five digits, etc. Some issuers require the expiration date and 'member since' or 'valid from' date. In this situation, the date field will be eight digits rather than four digits. To do this, the program obtains a variance from the standard. The card program and issuer establish what numeric information is encoded in this field, what it means, and how it is used.
- *I: End sentinel.* The end sentinel is encoded after the discretionary data field. The end sentinel informs the magnetic stripe reader that the data fields of the stripe are now encoded and no further data are encoded.
- *J: LRC.* The encoding of an F2F format for payment cards calls for an odd parity on each track. Each character has its own parity bit already; the LRC insures that the string of bits also has an odd parity.
- *K: Ending clocking bits.* After the LRC, there is another series of clocking bits to verify the timing of the synchronization process.

Track 2

This was developed by the American Bankers Association (ABA) for the automation of financial transactions and its encoded information is numeric only, limited to 40 characters, including the start sentinel, end sentinel, and LRC. The character configuration is 5 bits per character, including the parity bit, at a recording density of 75 bits/25.4 mm per inch.

Track 2 is located below track 1 on the magnetic stripe ([Figure 2](#)). There is a small separation between the two encoded tracks to prevent magnetic field interference during encoding and reading. Since a detailed description of each field for track 1 is given above, and the explanation is the same for track 2, only the function for each field is given:

- A: clocking bits
- B: start sentinel – HEX-B
- C: PAN
- D: field separator – HEX-D
- E: additional data or discretionary data field
- F: end sentinel – HEX-F
- G: LRC
- H: ending clocking bits

H	G	F	E	D	C	B	A			

Figure 2 The ABA track or track 2.

The hexadecimal (HEX) is a numeric system based on powers of 16. Valid hex digits range from 0 to 9 and A to F, where A is 10, B is 11, . . . , F is 15. In the above, HEX-B would be the encoded binary equivalent of '11,' and HEX-D is the binary equivalent of '13,' etc.

Track 3

This was developed by the thrift industry and is a numeric data-only track with 107 characters, which includes the start sentinel, end sentinel, and LRC (Figure 3). The encoded density of track 3 is 210/25.4 mm bits per inch with 5 bits per character. The information encoded in the use and security data and additional data fields is updated after each transaction, allowing a card encoded on track 3 to be used in online and offline systems. Since a detailed description of each field for track 1 is given above, only the function will be given for each field in track 3, as they, too, overlap:

- A: clocking bits
- B: start sentinel – HEX-B
- C: format code
- D: PAN
- E: field separator – HEX-D
- F: use and security data, and additional data field
- G: end sentinel – HEX-F
- H: LRC
- I: ending clocking bits

Optical Variable Device

The optical variable device (OVD), or hologram, is hot stamped to the overlay on the front or back of the card. These image foils may be two- or three-dimensional (2D or 3D). Some companies have trademark names for their OVD products, such as Gyrogram, Optoseal, Kinegram, Exelgram, etc.

Embossing

Embossing is the production of the 3D characters that rise above the front of, and are recessed in the back of, the card. The ISO Standard 7811-1 mandates the type/style for the account number as a Farrington 7B OCR type. The remaining material, alphanumeric, on the card can be any type of design as long as its size conforms to that allocated by the ISO standard.

Payment Card Fraud

Payment card fraud is, simply, the unauthorized or fraudulent use of a credit, debit, or prepaid card. Payment card fraud can be accomplished simply by stealing the victim's payment card account information, and does not necessarily involve

counterfeiting or physically stealing the victim's payment card. According to a survey conducted in December 2010, credit and debit card fraud have affected 29% of worldwide financial service customers.

Fraud schemes involving payment cards typically involve the theft and subsequent use of payment card account information. In some cases, the account information is stolen by the same individual or criminal group that ultimately uses the card. It has also become common for an individual or group to steal payment card account information and then sell this information to other individuals or groups, who then use the payment card information to make purchases. Stolen account information that is available for sale can range from a single account number to a package containing the cardholder's name, the account number, the card's expiration date, the CVV number, the cardholder's social security number, the cardholder's address, and the cardholder's mother's maiden name, among other items. These bits of information can also be purchased individually.

Criminal groups and individuals can use many methods to steal payment card information and commit payment card fraud. Several examples of payment card fraud schemes are listed below:

- *Account takeover*: This occurs when an existing credit, debit, or prepaid card is intercepted by or redirected to a criminal. Criminals often accomplish this by changing the address on an account, and then reporting the cardholder's real card stolen. Replacement cards are then mailed to the address provided by the criminal.
- *Application fraud*: This occurs when criminals use a stolen identity to obtain a payment card in someone else's name. This type of fraud is most frequently associated with credit cards.
- *BIN attack*: This fraud scheme occurs when thieves identify a functioning card's account number and expiration date, then change the last four digits of the account number using a number generator. This scheme is not likely to work if the issuing bank has used a random number generator to create account numbers instead of issuing sequential card numbers, all of which most likely would use the same expiration date. Bank identification number (BIN) refers to the first six digits of each account number that numerically identify the issuing bank.
- *Force post fraud*: In this scheme, thieves use a network-branded prepaid gift card with a zero-dollar balance to purchase items. Purchases under a specified dollar amount at certain merchants are often force posted, meaning that the transactions are not authorized at the time of the sale. (This process significantly speeds up the point-of-sale process at merchants such as fast food vendors and coffee shops.) Because some of these cards – specifically, network-branded cards that are sold in present dollar amounts – are typically sold and used anonymously, it is often difficult or impossible to track the criminal(s).
- *Hacking*: This occurs when a hacker is able to extract payment card account information from network transactions or access databases of stored payment card information. Hacking into such data sources can allow thieves access to millions of credit card numbers at a time. In July 2005, hackers used this method to steal the information

Figure 3 Track 3.

associated with 45.6 million payment cards from TJX-owned retail stores TJ Maxx, Marshall's, and HomeGoods.

- **Phishing:** These schemes, which rely on social engineering techniques, trick cardholders into voluntarily providing personal information, including but not limited to payment card information.
- **Skimming:** In these schemes, a device called a skimmer is used to capture payment card data from payment cards' magnetic stripes. Skimmers have been used to capture card data in restaurants, at gas pumps, at ATMs, and countless other locations. Skimmers are frequently used by Eastern European organized criminal groups operating in the United States.

Of the fraud methods discussed above, hacking and skimming likely present the greatest danger to payment card customers and financial institutions. Although popular opinion holds that online transactions are the most likely to result in stolen payment card information, these two fraud methods make brick and mortar merchants even more vulnerable than online retailers: in 2007, the majority of stolen payment card information was taken from brick and mortar retailers and restaurants. According to an analysis conducted by VISA, 83% of payment card information breaches occurred at merchants processing fewer than one million payment card transactions each year, with most thefts at restaurants.

Once a criminal possesses payment card information, there are several ways the information can be used to make fraudulent purchases of goods and services. The payment card information can generally be used as it is to conduct CnP transactions through online retailers or brick and mortar merchants if transactions are conducted over the telephone. If the criminal is unable to purchase the desired items or services using a CnP transaction, the stolen payment card information will need to be encoded on a magnetic stripe card.

Stolen payment card information can be encoded on any card that uses a magnetic stripe, including expired or canceled network-branded credit, debit, and prepaid cards; prepaid gift cards; hotel room key cards; or any other card with a magnetic stripe. The goal of these cards is not to look and feel like legitimate payment cards, but simply to interact with standard magnetic stripe readers found at points of sale. All that is needed to convert existing magnetic stripe cards into cards carrying stolen payment card information is a magnetic stripe writer, which can be purchased online for between \$200 and \$500 USD. A local drug-trafficking gang operating in a United States city used this technique to hide the proceeds of their crime from law enforcement agents. Members of the group purchased reloadable network-branded prepaid cards, which they used to launder the proceeds of illegal drug sales. To prevent law enforcement from recognizing and seizing the cards, the gang members used a magnetic stripe writer to encode the contents of each prepaid card's magnetic stripe onto a hotel room key card, effectively turning the hotel room key cards into duplicates of legitimate prepaid cards that contained laundered funds. Because each of the gang members wore several of the hotel key cards/prepaid cards on lanyards, law enforcement officials initially mistook the cards for mementos of gang members' sexual encounters.

Thieves can also create counterfeit cards, which is a significantly more complicated process. Card counterfeiters must

create a passable, but not a perfect, product. To be successful, counterfeit cards need only to pass a cursory inspection at point of sale. Because there are hundreds of card programs and tens of thousands of issuers, legitimate cards have a wide variety of appearances, making identification of counterfeit cards very difficult. A discussion of the production of counterfeit cards follows.

Counterfeit Plastic

Counterfeiters fabricate counterfeit cards using the same general techniques and similar equipment as a genuine manufacturer; however, there are typically distinct differences between legitimate cards and counterfeit cards. For example, counterfeit cards may be fabricated as individual cards, not as part of a large sheet of cards. Furthermore, counterfeiters are not obliged to adhere to the same quality and physical standards of a genuine card manufacturer. The card manufacturer must make a product that will last for years; the counterfeiter's card need only last for a couple of passes.

Counterfeit Printing

Some of the processes used to print counterfeit cards are offset, rainbow, screen, hot stamping, typographic or letterpress, thermal mass transfer, thermal dye diffusion, computer printers using transparencies that are then bonded to a plastic card, laser engraving, etc. Frequently, multiple printing processes are used to make a single counterfeit card. Linkage of cards based on the printing process used to print each area of the card is critical. Counterfeiters can, and do, share negatives and computer image software. They can, and do, make changes in the images they acquire, or they use a different combination of images and different printing process to print those images.

Counterfeit Holograms

The OVDs on counterfeit payment cards can be any of the following types: 2D and 3D holograms, hot-stamped images on diffraction foils, computer-generated images using commercially available silver and gold paper, etc. Image analysis and linkage of OVDs is critical to establishing a common source of these devices.

Counterfeit Signature Panels

The type of signature panel, or the printing methods used to make it, is very important in linking cards. The method of printing the panel or applying it to the card must be determined.

Counterfeit Embossing

Linking cards by the embosser or punch and die used to emboss material on the card is very effective. Embossers and embossing have unique characteristics that make them identifiable. The examination of embosser type is a 3D study: in [Figure 4](#), the 'X' coordinate is the width of the typeface, the 'Y' coordinate its height, and 'Z' is the depth of the impression in the plastic.

[Figures 5](#) and [6](#) show an embossing punch and die and describe each of its surfaces. Each surface shown can leave a

record of its presence on the plastic overlay surface of the card. These defects, together with the class characteristics of the punch and dies, and the machine, collectively are what make embossing identifiable.

When the card is examined, it is important to observe the presence of any defects on the overlay of the card (**Figure 7**).

Printed material on the core plastic, such as the text or planchettes added to the background printing, makes it difficult to focus on the top of the overlay. Since the overlay is only about 0.0015 inch (0.031 mm) thick, it is difficult to focus on its top surface and ignore the optical noise under it on the core. To illuminate the top surface properly, the angle of the light must be very small, as shown in **Figure 8**. Use of a stereomicroscope and fiber-optic light source is best for this examination. Varying the angle of the card and light to the objective in small increments allows the examiner to see the greatest overlay surface detail possible. The purpose of this examination is to reflect light off the surface of the overlay, because this is the surface where the striations and defects are located. The use of a comparison microscope is essential when comparing the striations on separate cards or a card with the punch and die from a suspected embossing machine.

Figure 4 The examination of embosser type is a 3D study. See text for details.

Figure 5 The parts of the embossing punch. This punch has a chip in the typeface and bevel, and striations on the typeface, bevel, and shoulder. These individual characteristic defects are recorded on the surface of the plastic during the embossing process.

Two other methods used to assist in the examination of the card overlay surface are the vacuum deposition of a thin, opaque, layer of metal over the surface of the card where the embossing is located. The evaporation of this thin film is applied to the card surface before the embosser examination begins. This thin metallic film covers the surface of the overlay where the embossing is located and acts as a first surface mirror, highlighting the defects. Because this thin film is opaque, the problem of optical noise caused by the background on the core is overcome. A second method is the use of Mikrosil casting material. While this is a good material to show chips and larger defects in the plastic overlay surface, it does not seem to work as well for very fine microscopic detail defects.

Not all of the embossed material on a card has to have been embossed on the same embosser or with punch and dies on the same machine.

Counterfeit Magnetic Stripes

In certain instances, it is possible to determine that two encoded magnetic stripes were encoded on different encoders, based on the characteristics of the encoder as recorded on the card's magnetic stripe. A special encoder analyzer is needed to

Figure 6 Defects (a chip and striations) in an embossing die.

Figure 7 Surface defects on the overlay of an embossed 'W.' These defects may be found on the front and back of the card, either on or near the embossed character, or inside it.

Figure 8 The relative angle of the light source to the card and the microscope objective for an examination of the overlay surface.

perform this examination. It is not just what information is encoded on the stripe but an analysis of that encoding to determine something about the characteristics of the encoder that is used that is important. If the encoded information on the stripe of two different cards is the same, a linkage by encoded information is possible.

Introduction

A multitude of disciplines evolved within forensic science during the twentieth century, resulting in highly specialized fields of evidential opportunities to support criminal investigations. Many of the more traditional disciplines, for example, footwear analysis and blood pattern interpretation, now have well-established principles and methodologies that have been proven in a criminal justice context; developments in these areas are largely confined to technical support systems and information sharing through databases. The very rapid rate of development of DNA profiling techniques during the 1980s and 1990s led to the emergence of national and international DNA databases; however, the pace of change has now significantly reduced. Conversely, the end of the twentieth century and the early part of the twenty-first century have seen an explosion of new forensic evidence types that are less established in court – disciplines such as CCTV, mobile phone, computer analysis, and the use of digital images and social media are collectively referred to as e-forensics.

Owing to the highly specialized nature of each forensic discipline and the varied rate of evolution, forensic science effectively represents a composite of interrelated, and often distinct, opportunities to support criminal investigations.

Most current models of forensic service delivery, especially where part of a wider organization, for example, police forces and enforcement agencies, have arisen over time by bolting on additional elements and clustering together within related fields. If the current capability of forensic science were to be designed from scratch as an effective entity, it is certain that a more integrated, and hence effective, structure would be proposed.

In addition, there has been a professionalization of forensic science in the workplace and increasing requirements for regulation; as recently as the 1980s, crime scene investigation, for

example, was widely undertaken by police officers and was largely restricted to recording/recovering visible evidence; this was used in a limited capacity to support that particular investigation without scope for wider intelligence development. Now, crime scene investigation is predominantly undertaken by specialist staff employed to exclusively undertake these duties.

To practice in a forensic discipline, specialized training, qualifications, and competency levels are required. The range of evidence types that have potential to support investigations has widened considerably. Some disciplines lend themselves to cross-skilling.

Public expectations of what forensic science can deliver have been heightened by highly popular mainstream television programs, both documentary and fictional. Often, the expectation of what can be delivered exceeds what is either possible or financially sensible. This leads to a requirement on service providers and users to make informed (evidential and financial) decisions regarding the best use of forensic evidence in support of investigations.

This article considers options to optimize the use of forensic evidence types recovered from crime scenes in the context of the different models available to criminal justice systems; the concept of integrated case management is outlined and discussed.

Task

To bring together all potential forensic evidential opportunities, holistically review their significance to the investigation, prioritize the progression of work, deliver the best evidence to the court for testing (complying with all continuity, integrity, and quality requirements), and ensure the best value for money when determining spend on forensic evidence.

Internationally, there are variable constraints and opportunities due both to the different criminal justice models and the commercial market situation at state/regional and country levels.

Models

- (a) All forensic evidence sourced within a law enforcement agency, for example, a police laboratory.
- (b) All forensic evidence provided by external specialists contracted to a law enforcement agency.
- (c) Composite of (a) and (b).

Forensic Strategies

The recovery of evidence from the crime scene is only the start of the forensic process. Once the evidence has been collected, packaged, and preserved, it needs to be analyzed in order to provide meaningful information to the investigation and subsequently the courts.

Forensic examinations are carried out in order to implicate or eliminate individuals and also in order to establish what has occurred during the commission of an offense or incident.

Deciding what analysis is required can be a complex process. Some of the issues for consideration include the following:

- Is it necessary to examine all the evidence that is recovered?
- Should every possible test be carried out?

In an ideal world, it would be preferable to carry out every possible analysis; however, in reality, it is likely that this will be neither practicable nor financially viable. In addition, carrying out every possible analysis would overload forensic laboratories.

When making decisions about what forensic analysis should be carried out, it is vitally important that consideration is given to both the potential prosecution and defense cases. An impartial approach must be taken to assessing examination requirements. It is often not necessary to carry out an examination of every item of evidence recovered, but examinations should be directed to where value could potentially be added to an investigation.

A forensic strategy should be developed around every case where forensic evidence plays a part, and may relate to an overall case or to an individual item of evidence. A forensic strategy should be developed in a holistic manner taking into account all potential evidence types and should direct and coordinate the forensic examinations/analyses that are required.

Forensic strategies can be developed in different ways by one or more of the following:

- Investigating officer
- Crime Scene Investigator (CSI) or Crime Scene Manager
- Forensic Scientist/Forensic Specialist
- Forensic Submissions Officer (Forensic Submissions Officer is a role that can be variably named; this role relates to an informed individual within a Police Force or Law Enforcement Agency who uses knowledge and expertise to advise on forensic analysis and who has decision-making

authority and control of the budgetary spend. May also be known as Forensic Advisor, Scientific Support Manager, etc.)

- Legal Representative
- Pathologist

Forensic strategies are generally initially developed and applied by individuals involved in the prosecution aspects of a crime. Although this is the case, it is vitally important that a balanced and unbiased approach is taken to the development of a strategy and consideration given to information that may support the defense case as well as the prosecution case. Examinations that are likely to add value or provide information to an investigation (irrespective of whether it will support or weaken the prosecution case) should be carried out and all results must be disclosed to the defense team. Defense should also be given the opportunity to carry out any review of strategies, examination processes, and/or results that they require and be provided with access to any items of evidence that they want to examine themselves in order to build the defense case.

In order to develop the forensic strategy and make appropriate decisions about which forensic examinations will be of value to the investigation, the following are necessary:

- To be able to gather as much information as possible about the circumstances of the case
 - circumstances of evidence recovery
 - accounts given by victim(s), witnesses, suspect(s), etc.
- To have an understanding and knowledge of forensic science and its application to investigations

A forensic strategy meeting is a useful way of ensuring that all relevant parties are aware of the full circumstances of the case and enables a 'multiagency' discussion about the processing of all exhibits to optimize evidential potential in a comprehensive and coordinated manner.

It can often be the case that police officers do not have a full understanding or knowledge of forensic science, likewise forensic scientists historically have had a relatively poor understanding of police and investigative processes; this can lead to miscommunication and confusion in relation to the application of forensic science to meet investigative needs. A joint approach to the development of forensic strategies helps to improve the communication and understanding on a case-by-case basis.

A formal forensic strategy meeting is often required only in more serious cases; however, the general approach can be applied to any investigation. Even in the most simple of cases, it is often beneficial for discussions to take place between the investigating officer, the CSI, the forensic advisor/budget holder/decision maker, and the prosecutor. Alternatively, generic strategies can be implemented, for example, for a particular crime type or *modus operandi*.

When making an assessment regarding the potential examination of a particular item and the development of a forensic strategy, the requirements of the investigation are the primary concern and consideration should be given to the following issues:

- The type and nature of the item/exhibit
- The context of the item
 - Exactly where and when it was recovered
 - Condition of the item, that is, wet, damaged, etc.

- The integrity of the item
 - Has it been appropriately recovered, handled, packaged, and preserved?
 - Is the security and continuity of the item intact?
- The potential evidence that may be obtained from the item, for example, DNA, fingerprints, fibers, footwear marks
- The information these evidence types may provide to the investigation
- Whether this potential information is likely to add value to the investigation
 - Is it possible that new information will be provided?
 - Is it possible that an account given by a witness, victim, or suspect will be supported or refuted?
 - Will the information help to establish what has occurred?
- Whether there is a conflict between potential evidence types, and if so, which evidence type will be of most value under the circumstances
 - For example, swabbing/taping for DNA may damage fingerprints, but where the DNA is likely to be at low levels and requires specialized low-template DNA analysis, the presence of DNA may not necessarily prove contact with an item, whereas fingerprints will always prove that contact has occurred
- The chances of success, that is, obtaining a result/information of value to the investigation (this may be inclusive or exclusive)

Much work has historically been completed in relation to developing and understanding the success rates relating to DNA profiling; however, relatively little work has been undertaken to fully understand the success rates associated with other forensic evidence. This is largely due to the fact that other evidence types, such as fibers, gunshot residue, footwear marks, etc. are generally more complex to interpret than DNA. In relation to DNA profiling, success rates are generally based on the chances of obtaining a DNA profile; however, with the other evidence types, the value of the outcome is very much dependent on the circumstances of the investigation. For example, when searching an item of clothing taken from a suspect for glass, the absence of glass or the presence of glass could both be of value to the investigation depending on the circumstances. The presence of glass on the clothing that matches control sample(s) from the crime scene is only of value if its presence cannot be accounted for in any legitimate way; conversely, the absence of glass on the item of clothing may lead to a conclusion that the suspect was not involved in the offense, depending on the circumstances of the offense and arrest.

In addition to being able to understand and evaluate the chances of being able to obtain a meaningful result, it is also vital that the value of the overall contribution to the entire case is understood. This involves being able to understand the value and contribution of the forensic examination to the detection of the offense as well as the outcome of the court process. This is an even more difficult issue to evaluate and understand than the chances of being able to obtain a forensic test result.

Because the value of forensic evidence is so dependent on the individual case circumstances, decisions about examinations must be made on an individual case basis. There have

been recent developments in some agencies/Forces to better understand the chances of success of different types of forensic evidence and the value to investigations; this will help to better inform decisions about evidential potential and examination viability as well as assisting to achieve value for money. This approach is best described as *forensic effectiveness*.

The forensic strategy should also take into account the timescales associated with the investigative process and the criminal justice system, and it should be ensured that forensic analysis can meet the requirements of the criminal justice process, including court dates and any requirements to disclose appropriate information to the defense team(s).

Each police force/law enforcement agency will have its own approach to the submission of exhibits for forensic examination/analysis; irrespective of whether the analysis is carried out in an internal police laboratory, external commercial company, or government owned laboratory, these approaches can be applied to all examinations and all evidence types.

These approaches help to ensure that decisions are made based on scientific knowledge, viability, and evidential value taking into account all aspects of the investigation. They will help to ensure that the best evidence is obtained while considering value for money and that it can be applied to any investigation irrespective of the seriousness of the offense or the scale of the investigation.

Integrated Case Management

The concept and use of forensic strategies in directing investigations is not new, but is often limited by the evolved structure of forensic disciplines within investigative agencies. Classically, DNA and fingerprint evidence from volume crimes will be independently submitted at the same time by different routes and this often results in wasted effort/spends and duplicated results. The development and use of forensic intelligence has been variable. Emerging thinking includes organizational redesign of forensics to better integrate with related functions such as intelligence collection, targeted deployment of resources, and prioritized forensic submissions.

The concept of integrated case management draws together informed operational deployment (e.g., of crime scene investigators) followed by a more holistic approach to submissions for testing. The strategy takes greater account of supporting intelligence and desired outcomes. Regular reviews and trigger points are included for the staged submission of potential evidence, and communication with investigators is enhanced so allowing for a more responsive and directed investigation.

Ultimately, the production of *intelligent identifications* can be better achieved by having an integrated process that links the enforcement priorities, available resources, potential forensic evidence, intelligence, and prosecutor requirements; this model provides flexibility to respond to changing demands and gives an increased likelihood of efficient and effective spend on forensic support to investigations. There is no single way to achieve this, but an illustration of how to rethink some of the traditional silo-based forensic disciplines is provided in [Figure 1](#).

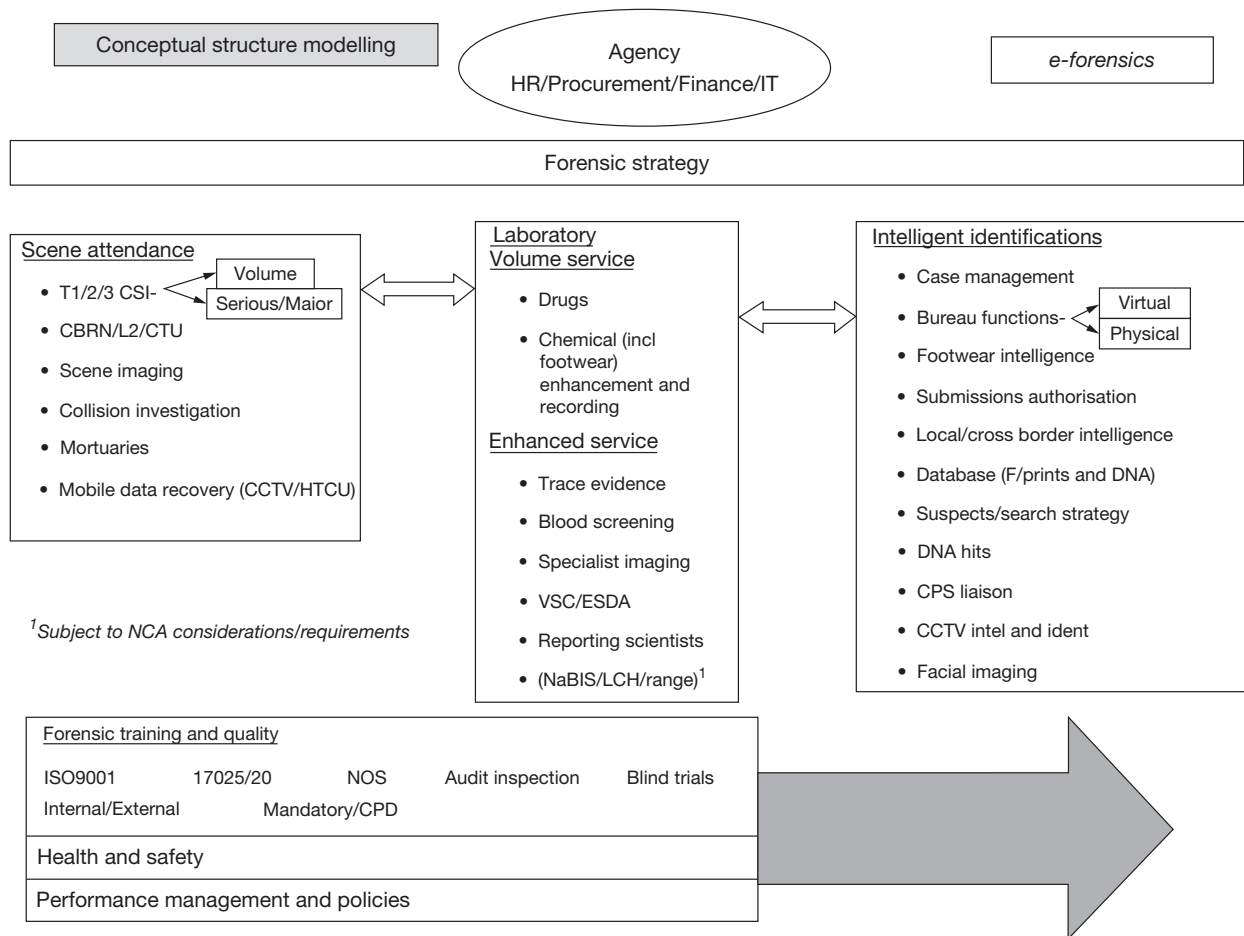

Figure 1 Conceptual structure modeling.

Summary

The single biggest challenge to the forensic science community during the twenty-first century is to modernize delivery of integrated services in support of investigations. This must:

- build on the previous development of each discipline;
- accommodate the new and emerging technological disciplines;
- meet the regulatory requirements;
- reflect the changing workforce and skills;
- deliver the best evidence to courts in support of investigations.

Glossary

Deflagration (or rapid burning) A reaction propagated by heat transfer.

Detonation A reaction propagated by a shock wave.

DVI or disaster victim identification The process of identifying victims of major disasters where visual recognition may not be possible. DVI involves the comparison of fingerprints, dental records, and/or DNA samples with those stored in databases or taken from victims' personal effects.

EOD or explosives ordnance disposal personnel Army personnel who in many jurisdictions have defined roles and responsibilities in the management of explosives scenes. Bomb technicians and bomb squads have similar roles.

FTIR or Fourier transform infrared spectroscopy A means of rapidly identifying some single compounds or the components of simple mixtures.

Gas wash Scouring of the surface of a metal by hot gasses generated by an explosion.

High explosive One capable of detonation in normal use.

High-order detonation A detonation in which the entire high explosive charge is consumed by the reaction; i.e. the reaction goes to completion.

HMTD or hexa methylene triperoxide diamine An improvised high explosive containing peroxide groups.

IED or improvised explosive device Colloquially a 'bomb'; that is a device comprising a number of components

designed to initiate a main explosive charge. It is improvised in the sense that it is not military or commercial in origin but may include such components.

IMS or ion mobility spectrometry A means of rapidly detecting target compounds.

LIBS or laser-induced breakdown spectroscopy A means of rapidly detecting chemical elements of interest.

PETN or penta erythritol tetra nitrate A military high explosive that also finds application as a pharmaceutical.

Plastic deformation Irreversible change in the shape or size of an object in response to the temperatures and pressures generated by an explosion.

Propellants Explosives used to propel projectiles and often including nitrocellulose.

Pyrotechnics Explosives designed to produce effects such as heat, light, sound and/or smoke.

Raman spectroscopy A means of rapidly identifying some single compounds or the components of simple mixtures.

RDX or research department explosives A military high explosive.

Spectra A collective and broad term for the output of a variety of detection systems.

TATP or triacetone triperoxide An improvised high explosive containing peroxide groups.

TNT or tri nitro toluene A military high explosive.

Preface

In order to get best value from this article, it is important to be familiar with the basic chemistry and physics of explosives. It is recommended that the article on Mechanisms of Explosion is read first. The articles on Improvised Explosives and Commercial and Military Explosives also provide useful background information.

Scope

There are a variety of events that might be described as an explosion, for example, the rupture of an overpressurized vessel or the ignition of a flammable gas or liquid. Many explosions are the subject of civil proceedings and/or accident investigation and may be the result of criminal negligence. However, this article focuses on explosions that involve energetic materials in the condensed phase. The article covers the criminal misuse of explosives, particularly by terrorists, primarily as part of improvised explosive devices (IEDs), otherwise known as bombs; and the forensic investigation of post-explosion scenes resulting from the functioning of IEDs.

It must be recognized that postexplosion scenes are extremely complex. This article can only present a broad approach to scene management and the recovery of forensic evidence. It describes general principles rather than providing a detailed plan applicable to every scene. Each postexplosion scene is unique and brings with it its own challenges in terms of management and forensic recovery.

Introduction

Explosions, of the type dealt with in this article, are often the result of an attack by terrorists. Explosives remain, as they have for hundreds of years, a popular component of terrorist weapons. Explosives, by virtue of their chemistry and physics, have the capacity to do a large amount of work by releasing large amounts of energy (kJ g^{-1}) in a very short period of time (μs) and generating very high pressures (GPa). A small amount of explosive provides a significant amount of destructive force. This capacity to injure people and damage property and infrastructure makes explosives-based weapons an attractive proposition for the terrorist.

Among the main objectives of the forensic investigation of explosions are to safely and efficiently recover evidence and to ensure that the evidence recovered is fit for purpose. These objectives might be summarized as: to maximize forensic exploitation. The purpose referred to is to being the investigation to a successful conclusion by ensuring that perpetrators and any associates are quickly identified, arrested, and, in due course, successfully prosecuted.

When faced with a possible postexplosion scene, the first two questions requiring an answer are:

1. Has an explosion occurred?
2. If so, what type of explosion was it?

It should be established as early as possible whether or not the scene is a postexplosion scene. This is usually quite clear from the damage and destruction observed, images recorded, and witness accounts. However, circumstance may delay the receipt of that information. In the London bombings of July 2005 where initial explosions took place in underground tunnels, it was nearly an hour before it was accepted that explosions had occurred.

The Initial Response

The first step in the process of scene management and forensic exploitation is to gain control of the scene. This is a major task in itself and perhaps the major challenge. Law enforcement agencies (and other first responders) worldwide have detailed plans for managing and investigating large postexplosions scenes. The problem with postexplosion scenes is that apart from some very broad similarities, each presents challenges that are unique. The successful forensic exploitation of such scenes requires careful consideration and planning, usually in the face of significant time pressure.

After a large explosion has taken place, first responders will include fire and rescue, medical services, and police. Fire and rescue and medical services will not have forensic exploitation and the needs of a criminal investigation as high priorities. Indeed the preservation of life and the treatment of casualties must always be the first priority. More recently, disaster victim identification has been added as a close second. Managing conflicting priorities is another major challenge in the successful investigation of explosives-related crime involving major postexplosion scenes.

As fire and rescue and medical services will almost certainly be among the first to attend a postexplosion scene, it is important that they have some forensic awareness training. Forensic awareness will help to ensure that in undertaking their essential and important tasks they do as little as possible to compromise the scene by inadvertently/unknowingly contaminating the scene or taking evidence away or in some other way affecting the evidence present.

It should be recognized that casualties themselves will be evidence in terms of the injuries suffered and/or vectors for evidence such as shrapnel retained by tissues and perhaps chemical evidence.

Postexplosion Scene Control

Gaining control of the scene is in reality a gradual process and usually only occurs once casualties have been evacuated. In very broad terms, the first step is to place a cordon around the scene usually at a radius of between 100 and 200 m with the seat of explosion as the center point. The actual radius will depend on a number of factors including the size of the debris field and the type of environment. It should always be borne in mind that it is far easier to reduce the radius of a cordon than increase it. The purpose of the cordon is to preserve the scene, allow a systematic and effective recovery of evidence, control access and movement, and allow forensic recovery to be undertaken undisturbed and safe manner. The cordon may need to extend vertically by imposing a no-fly zone. Cordons are often legally enforced and the unauthorized crossing of a cordon is an offence under relevant legislation. Suitable access points need to be identified and manned to record all movements in and out of the scene.

Once the cordon is in place the scene must be surveyed, accurately recorded as it is, and made safe for forensic investigation and recovery to begin. The health and safety of those working in the scene must be considered. In some jurisdictions, managers and employers owe a legal duty of care to their staff. Postexplosion scenes are inherently hazardous and this must be accepted. Nevertheless, those responsible must do all that is reasonable to assess and manage risks to those operating at the scene. In particularly hazardous environments, this may include limiting the time spent by individuals locating and recovering evidence.

Health and Safety

At postexplosion scenes, the two ever-present hazards are buildings in various stages of collapse and explosives.

In some jurisdictions, bomb technicians, usually specially trained army explosives ordnance disposal (EOD) technicians, have a defined role. One of the first steps in gaining control of the scene is for the scene to be formally handed over to EOD personnel. EOD technicians then conduct a survey of the scene which might include a canine sweep, take whatever action is necessary to make the scene safe, declare the scene explosively safe, and then hand the scene back to the lead agency, usually the police.

In terms of structural safety, it is often wise for a structural engineer to survey the scene and determine what actions need to be taken to manage risks and protect those working in the scene. Risk mitigation might include imposing a no-fly zone.

Clearly other experts might need to be called to assess and help manage other risks, such as contamination of the environment with hazardous substances.

Each postexplosion scene is unique, and careful consideration and planning are required to assess and manage risks. However, the reality is that often the scale and political enormity of the event are such that all responders can do is their best under very difficult and demanding circumstances. Those

involved in responding to, preserving life at and the investigation of major postexplosion scenes should be commended for their courage and commitment in getting the job done.

Preparation and Planning for Forensic Recovery

Once the scene is under control, access should be limited to essential personnel whose purpose is forensic exploitation.

While the recovery of explosives evidence is often a priority at postexplosion scenes, other evidence types need to be given consideration and the preparation of a forensic recovery plan is often essential. It is unlikely that any plan will be completely adhered to but the exercise is useful for highlighting issues, ensuring effective communications and promoting good practice; planning is indispensable.

All those entering the scene should wear barrier clothing; this is to prevent them contaminating the scene and indeed the scene contaminating them. This is in addition to any personal protective equipment that individuals might require to reduce risks to their safety.

Next steps might vary but the creation of a common approach path can contribute to successful exploitation. A common approach path links the access point on the cordon and the seat of the explosion. The path is prepared by clearing debris to one side. This is the only path used and it is used by all.

There are now sophisticated tools available for crime scene surveying and mapping but the essential requirement is that forensic recovery is done in a rational and systematic way. The object is to determine the cause of the explosion; the construction, components, and functioning of the explosive device; and the nature of the explosive charge(s). Therefore, both physical and chemical evidence needs to be located and recovered.

Scenes should be surveyed, mapped, and recorded and a detailed record of activities within the scene made.

Some or all forensic recovery can take place within the scene. Chemical recovery of traces from or in proximity to the seat of the explosion(s) may have to be done in situ. However, it is often preferable that any item of potential evidence that can be removed from the scene should be identified, recorded, appropriately packaged, and submitted to a forensic explosives laboratory for examination. It is also preferable that general debris itself be removed from the scene for search in a specialized facility or at least using specialized equipment.

The precise details of chemical and physical recovery will change with each scene and plans vary among agencies. However, the essential objective is to maximize forensic recovery within the constraints that will apply and ensure evidence is fit for purpose.

Contamination Control, Continuity, and Evidence Integrity

These issues should be given careful consideration when formulating a forensic recovery plan.

If the main explosive charge was a high explosive and the reaction was a high-order detonation, then the likelihood is that little chemical evidence of the explosive charge will remain. Such chemical evidence that does remain is likely to fall into the category of trace evidence. The term 'trace' is usually reserved for submicrogram quantities. Therefore, those working in the scene will need to exercise caution in terms of contamination control so as not to adversely affect the integrity of the evidence.

While the involvement of bomb or EOD technicians at a postexplosion scene is essential, they should be considered an uncontrollable source of explosives contamination. A record of their movement within the scene must be made and retained. Any area visited by them should be excluded for the purposes of trace sampling. If at all possible, they should be kept away from the seat of the explosion, should only touch items when essential, and should give any bodies remaining at the scene a wide berth as those bodies may bear crucial trace explosives evidence.

If a canine sweep or search has been conducted, then the same precautions and consequences would apply to the dogs.

Continuity is guaranteed and evidence integrity maintained by adopting the following practice. Barrier clothing is worn by those recovering evidence. The item is recovered into a nylon bag. The nylon bag is sealed airtight and accurately labeled with descriptive and other information. The information should include the time and date of recovery, its recovery location, the identity of the person recovering the item, and a unique identifier. Each item recovered should be logged out of the scene as it crosses the cordon.

For the recovery of explosives traces, quality assured and specially manufactured sampling kits must be available. Quality assurance provides a guarantee that the sampling kit is explosives free before use. Evidence that the kit has been used in accordance with its instructions is essential. These measures will ensure that any trace explosives evidence recovered is fit for purpose.

What Might be Recovered?

Explosive devices come in many forms but require two essential components:

- an explosive charge and
- a means of initiating the charge.

It is the determination of the nature of these two components that forms the basis of forensic recovery from a post-explosion scene.

In addition to the two essential components, the explosive device might also include:

- an explosive train – a collection of different types of explosives intended, for example, to convert a flame or an electric current into a detonation, for example, a detonator or fuse;
- electrical components such as wires, batteries, light bulbs, and light emitting diodes;
- timing devices (mechanical and electronic);

- adhesive tapes;
- vessels (containing and/or confining);
- shrapnel (nails and screws);
- sensors (proximity and movement); and
- switches (mechanical and electronic).

Explosive devices can be incorporated into vehicles, concealed in everyday items such as bags, or carried by suicide bombers.

Larger remains of the device can usually be identified by the type of damage sustained and distance from the seat(s) of the explosion(s).

The remains of the device are best recovered by sifting debris. Using mechanized systems, tons of debris can be sifted either at the scene using transportable systems or at specialized facilities. When competently performed, many fragments of the explosive device may be recovered enabling the forensic scientist to reconstruct the device.

Types of Explosives

There are broadly two types of explosives to consider: detonating and deflagrating (burning). A detonating explosive, gram for gram, will usually provide more destructive force than a deflagrating explosive. Therefore, scenes of major destruction, for example, the Oklahoma Bombing in 1995 and the Bali Bombing (Sari Club) in 2002 can be identified as having been caused by a detonating explosive. However, smaller scale incidents such as the London Soho Bombing (1999) need some chemical information to reliably identify the type of explosives involved.

Recovery of Chemical and Physical Evidence

Identifying the explosive involved is a high priority task and is often a challenging aspect of forensic exploitation. Explosives undergoing a high-order detonation would be expected to leave little by way of chemical traces. Therefore, examination of items exhibiting damage consistent with proximity to such a detonation may be all the evidence that remains of the explosive.

A property of high explosives is brisance or shattering ability. Damage such as irregular fracture provides evidence of a detonating explosive, as does plastic deformation of metal, gas wash, and microscopic cratering resulting from the impact of high velocity particles at very high temperatures generated by the detonation. Plastics may also exhibit characteristic melting.

As a result of their chemistry and the physics of the process, deflagrating explosives are often recovered postexplosion in an unreacted state. Propellants such as smokeless powders (nitrocellulose) and pyrotechnics such as potassium perchlorate/aluminum mixtures are often used as an explosive charge in pipe bombs where the explosive charge is confined within a vessel. Rupture of the vessel, as it fails when subjected to the increasing pressure from the gaseous products of the deflagration, often leads to a quenching of the reaction resulting in unconsumed explosives charge being available for recovery postexplosion.

Where the explosives charge(s) is military or commercial explosives, standard methods exist for their analysis and detection. In cases where the explosion was caused by an improvised explosive, an additional challenge exists. The use of improvised explosives may result in their nondetection using standard methods. In such cases, evidence from the bomb factory or documentation from premises may provide evidence of the nature of the explosive used. However, if the explosive is novel, then methods of analysis and detection will need to be developed and validated ad hoc.

Should bulk explosive be present at a postexplosion scene, then a range of sophisticated field deployable instruments are available to provide a rapid and, in certain circumstances, a fairly reliable initial identification of substances recovered. Such results should be treated with caution until confirmed by laboratory-based systems incorporating both separation and detection. The field deployable systems are based on Fourier transform infrared and Raman spectroscopy and ion mobility spectrometry. Systems based on laser-induced breakdown spectroscopy might also be useful. When faced with pure substances, or relatively simple mixtures, producing fairly complex spectra, these instruments can produce reliable results. However, when faced with explosives producing simple spectra, complex mixtures, or explosives contaminated with nonexplosive components, then results may be unreliable and misleading. Therefore, caution must be exercised and results should be confirmed, or otherwise, using laboratory-based systems.

Evidence from Bodies

The types of injuries suffered by casualties (bomb victims) and shrapnel collected by tissues are often of high evidential value. The relationship between bombing and injuries is beyond the scope of this article but suffice it to say that there are typical injuries. The collection of shrapnel is important. Shrapnel comprises fragments of material traveling at high velocity, produced by the explosion, and originating from the explosive device itself or materials in proximity at the time of the explosion. Casualties and victims should be examined and ideally x-rayed to locate, recover, and identify the source of the shrapnel. Shrapnel may help to identify components of the explosive device and shed light on its function. Chemical examination may help to identify the explosive constituents of the device.

Incident Reconstruction

It is important not to rush to conclusions. Postexplosion scenes can be particularly complex. Initial hypotheses and propositions often prove to be incorrect.

The scene must be accurately surveyed, mapped, and recorded as early as possible. The seat(s) of the explosion(s) should be located and recorded. The spatial relationship between debris and the seat can provide useful information. When the seat of the explosions is not easy to locate, a careful study of the debris field will assist.

Determining the components of the explosive device, its function, and the nature of the explosives charge(s) are

priorities. Apart from providing evidence to aid the reconstruction of the incident, such evidence may help to identify suspects and locations. The identification of the perpetrators, their associates, and locations, such as the bomb factory, are among the top priorities for investigators who will be under considerable pressure to achieve these objectives at the earliest juncture.

The forensic exploitation of a bomb factory follows similar principles to that of postexplosion scenes, but as no explosion has taken place it is beyond the scope of this article.

Interpretation

Interpretation can be considered in two contexts:

- helping investigators by providing timely and reliable evidence to aid the investigation and
- helping the court by providing reliable evidence to ensure a fair trial and secure the conviction of those who have committed offences.

In aiding the investigation, the answers to the two key questions need to be rapidly provided.

1. Has an explosion occurred?
2. If so, what type of explosion was it?

While it is often obvious that an explosion has occurred, for example, the first attack against the World Trade Centre (1993) or the Oklahoma Bombing (1995); that is not always the case. Air accident investigations are a good example of where it can take some time to reliably determine whether or not the accident was caused by a bomb. Furthermore, in Bali (2002) initial reports were of fires caused by the rupture of a gas tanker and in London (2005), because the initial explosions occurred in underground tunnels, it was some time before it was realized that explosions had occurred.

Once it has been established that an explosion has occurred the next question is whether the explosion was the result of a criminal act. Not every scene of major destruction caused by an explosion is the result of criminal activity.

Eye witness accounts may be helpful in this respect as will inspection of images that may have been recorded of the scene.

For the forensic scientist, the focus must be on finding, collecting, and processing physical and chemical evidence. That evidence must be reliable and fit for the purpose of investigation and later the court.

The interpretation of observations, findings, and results obtained by the forensic scientist in relation to post-explosion scenes may not be straightforward. Bombs can vary in magnitude and complexity from the Oklahoma bomb, perhaps the largest and most sophisticated IED yet constructed, deployed, and fired, to simpler and much smaller devices involving wires, a battery, an improvised initiatory system, and a main charge comprising a kilogram or so of improvised explosives.

Given the variety of IEDs, it is hard to generalize but the remains of the device should be identifiable by the type of damage sustained as a result of exposure to high temperatures and pressures, and high-velocity fragments. Typical damage sustained by materials in proximity to a detonating explosive

is well characterized and set out in a number of studies. While the damage sustained is not conclusive proof of explosives involvement, items exhibiting typical damage when assembled and other evidence taken into account usually allow for an accurate reconstruction of the improvised explosives device.

Interpreting the results of chemical detections is also a challenge. The nature of the explosive charge(s) can present difficulties. Where bulk explosives are recovered postexplosion, which is often the case with propellants or when a detonating explosive charge has not reacted full order, the task can be straightforward. However, when relying on trace detection there are general chemical issues related to matrix effects and selectivity. In addition, there are issues related to the particular type of explosives. Explosives can be classified as peroxide (hexa methylene triperoxide diamine (HMTD) and triacetone triperoxide (TATP)), conventional organics such as research department explosives (RDX), tri nitro toluene (TNT), and penta erythritol tetra nitrate (PETN), those incorporating inorganic compounds such as ammonium nitrate and, most recently, those relying on concentrated hydrogen peroxide as the oxidizer.

Although rare, trace quantities of conventional organic explosives have been detected in the environment and some nitrate esters are components of certain pharmaceutical products.

The trace detection of inorganic compounds involves the detection of individual ions and an association is not proved. The detection of ammonium and nitrate ions does not prove the presence of the inorganic oxidizer ammonium nitrate. However, other evidence may add weight to a proposition that the explosive charge included inorganic compounds.

Most inorganic species of explosives significance, such as nitrate and chlorate ions, are present in the general environment and therefore their detection at trace levels is often of limited evidential value.

The potential sources of peroxide explosives and their unique usage means that the detection of these species at trace level is of high evidential value. There is no reasonable nonexplosive explanation for the presence of these substances even at trace level.

The trace detection of postexplosion residues resulting from hydrogen peroxide-based explosive charges, such as those used in the failed London bombings in 2005, is in its infancy and it is difficult to suggest what evidential value the trace detection of such residues would have. Should unreacted material be recovered, then the concentration of the hydrogen peroxide may be of high evidential value.

Political Considerations

Terrorist bombings often target transport systems or critical infrastructure. Disruption to the economic activity of a major city or a nation, while in no measure equaling the grief and pain of those affected by the tragedy of a major terrorist attack, is an important consideration for politicians. In a democracy it is politicians who are ultimately responsible for the investigation of a postexplosion scene. If the attack has, for example, led to the closure of part of the transport system, there will be pressure to restore services as soon as possible without compromising the investigation, which is aimed at ensuring perpetrators and their associates are

quickly found, arrested, and, in due course, successfully prosecuted. This is a difficult balance to strike but pressure to reopen the airport or get the trains running is a reality of the investigation of explosions and is an issue for lead agencies. Managing competing priorities is among the major challenges of the investigation of explosions.

Summary

In the forensic exploitation of postexplosion scenes, health and safety must be paramount. Exposing scene workers to unnecessary risks and potentially adding to the number of casualties may therefore be counterproductive. In addition, unplanned or ill-considered actions may compromise evidence at the scene. On the other hand, delaying medical assistance to casualties while procedures are complied with may be considered unacceptable. Many major postexplosion scenes give rise to this dilemma and by far the most common action is to rush in and try to save lives; forensic exploitation and recovery usually come second. In that vein, the main steps in a successful forensic exploitation of a postexplosion scene are:

- Control
- Manage risks
- Survey
- Plan

However, taking major incidents such as Oklahoma, Bali, and London as examples where the preservation of life was a first priority, the investigations had successful outcomes. Perpetrators and associates were rapidly identified, arrested (if still

alive), and successfully prosecuted. Those involved in these investigations should be commended.

Overview of the Innocence Project and Innocence Network

The Innocence Project is a pro bono legal services organization affiliated to the Cardozo Law School at Yeshiva University in New York City devoted to utilizing postconviction DNA testing to exonerate wrongly convicted innocent individuals, and to reforming the criminal justice system to minimize the risks of wrongful convictions. The Innocence Project is actually just one – one of the first and the most prominent – of a growing network of independent innocence projects dedicated to exonerating wrongly convicted individuals with compelling new evidence of their innocence. Under a licensing agreement with the Innocence Project, many of those projects bear variations of the name 'Innocence Project,' such as the Innocence Project Northwest (in Seattle, WA), the Wisconsin Innocence Project, and the Innocence Project New Orleans (to mention just a few). Others operate under other names such as the Center on Wrongful Convictions (in Chicago), the Michigan Innocence Clinic, and the North Carolina Center on Actual Innocence.

Although all operate independently, these projects have formed an affiliation organization known as the Innocence

Network. As of June 2011, the Innocence Network counted 66 projects in its membership – 55 in the United States and 11 more in Canada, Great Britain, Ireland, Australia, New Zealand, and the Netherlands, with new organizations being formed in other regions of the world as well.

Some of these projects follow the model of the flagship Innocence Project in New York and handle only cases in which DNA evidence is available to prove innocence. A larger number of projects now accept cases in which other types of evidence, in addition to DNA, can also be found or developed to prove innocence. Recently, a few projects have formed that handle only the latter types of cases – non-DNA-based claims of evidence.

Because the various innocence organizations are independent and are created in various locations under various circumstances, they do not follow any one set or prescribed organizational structure. Many projects are affiliated with law schools and operate as clinical programs in which law students work on cases under clinical faculty (attorney) supervision, investigating and litigating the claims of innocence. Others operate as independent nonprofit organizations that provide internships for law students from a number of separate law schools within a geographical area. Still others have no real

law-school affiliation, and instead operate either as stand-alone nonprofit legal organizations or collectives of pro bono private attorneys. As a requirement for membership in the Innocence Network, however, all must have dedicated staff, and must agree never to charge clients for their services.

Not all innocence organizations provide direct legal representation to prisoners who claim to be innocent. Some are instead investigation projects that do not themselves provide legal representation to prisoners, such as undergraduate criminal justice programs, or investigative journalism projects. When such projects develop compelling new evidence of innocence, they typically refer the cases to pro bono attorney organizations or otherwise arrange legal representation for the wrongly convicted individuals. Still another new type of project provides support services to exonerees after their release from prison.

History

Beginnings of a New Movement

The Innocence Project formally opened its doors in New York in 1992. The Innocence Project, however, was not the first such organization devoted to proving the innocence of imprisoned individuals. Centurion Ministries in Princeton, New Jersey, had been doing that work for approximately 10 years, beginning in the early 1980s, and might be the first of such organizations. Centurion Ministries was created by James McCloskey, a former business executive who turned to the ministry, as an outgrowth of his chaplaincy work. Centurion Ministries, which remains active today, is not a traditional legal services organization. It has no legal staff, but instead focuses on in-depth factual investigations to find the evidence that can prove innocence. Once sufficient evidence of innocence has been found, Centurion Ministries hires or otherwise arranges legal counsel to litigate the claims of innocence.

The emergence of the Innocence Project, however, marked a dramatic new awakening in the criminal justice system to the reality and magnitude of the problem of wrongful convictions. The Innocence Project launched this new era – that has been variously described as ‘the innocence movement,’ the ‘innocence revolution,’ or the ‘age of innocence’ – primarily through the power of DNA evidence. The DNA exonerations, for the first time in the history of the criminal justice system, began to generate a surprisingly large and growing pool of cases in which we knew with near certainty, based upon scientific analysis, that the criminal justice system had erred. The DNA exonerations put to rest the myth that the wrongful conviction of an innocent person was an ‘unreal dream.’ At the same time that the DNA cases proved beyond dispute the reality of error, it attached real human names and faces to the problem of wrongful convictions – it generated stories of real people whose lives had been destroyed by misfiring of the criminal process, stories that powerfully moved the public, the courts, and policy makers alike.

Leading the way in utilizing DNA to exonerate the innocent in the early days of forensic DNA analysis were two New York lawyers, Barry Scheck and Peter Neufeld. Drawing on their experiences in high-profile cases in which prosecutors had begun to use DNA, Scheck and Neufeld realized the potential

for DNA to prove innocence as well. The two created the Innocence Project in 1992, at a time when there had only been a total of five DNA exonerations of wrongly convicted individuals in the United States (or anywhere else, for that matter). A year later, in 1993, a group of volunteers formed the Association in Defence of the Wrongly Convicted, launching the innocence movement in Canada. Nineteen years after creation of the Innocence Project, as of June 2012, the number of known DNA exonerations in the United States had grown to 292, largely, although not entirely, as a result of the work of innocence organizations across the country. At least 135 additional individuals had been exonerated by innocence projects using evidence other than DNA, and an untold number of individuals had been exonerated by non-DNA evidence by attorneys outside the Innocence Network.

New Projects and Emergence of the Innocence Network

In the following years, several additional innocence organizations formed, starting in Washington, Illinois, Wisconsin, and California. In 2000, Scheck and Neufeld, joined by *New York Times* writer Jim Dwyer, published their influential book *Actual Innocence* that told the story of many of the first DNA exonerations, and, for the first time, in a comprehensive way, sought to analyze the sources of error in these DNA-proven wrongful convictions. The book identified eyewitness identification error as the most frequent contributor to false convictions, joined by false confessions, flawed forensic science evidence, perjured jailhouse informant or ‘snitch’ testimony, prosecutorial and police misconduct, and inadequate defense counsel. In addition, Scheck, Neufeld, and Dwyer charted a course for the future of the innocence movement, setting a goal of establishing innocence projects across the country “that will represent clients in DNA and non-DNA cases,” and of creating an Innocence Network.

In 2003, leaders from a number of the nation’s emerging innocence organizations formed a steering committee to work on creating the Innocence Network envisioned by Scheck, Neufeld, and Dwyer. In 2005, the Innocence Network was formally organized, with a board of directors elected by the membership. As of 2011, 66 innocence organizations had joined the Network, most in the United States, but 11 scattered among Canada, the United Kingdom, Ireland, Australia, New Zealand, and the Netherlands. In the United Kingdom, the Innocence Network UK, which as an entity is a member of the Innocence Network, is itself an umbrella organization for over 20 member projects in universities. In the spring of 2011, the Innocence Network hosted its first international innocence conference, which drew participants from virtually all regions of the world, and foretold likely further expansion beyond these English-speaking common-law countries.

The Educational Mission

Place in Clinical Legal Education

Many, although not all, innocence organizations in the United States operate as law-school-based clinical educational programs. Beginning in the 1960s, clinical programs have become an increasingly important part of legal education in the United

States. Through clinical programs, law students learn to become lawyers in part by representing real clients in real cases, under the supervision and instruction of licensed clinical faculty.

Legal educators soon learned that innocence cases offer uniquely rich and challenging contexts for pedagogy. Even more so than many other clinical programs, innocence organizations involve students in extensive fact investigation. They offer a learning model that is quite different than the traditional law-school focus on appellate opinions, in which the facts are presented as a given or even insignificant. At the same time, innocence cases provide a valuable opportunity to examine the criminal justice system from the back end, by deconstructing cases that have already been tried and appealed, and in which the system failed. Moreover, the size, complexity, and unpredictability of innocence cases pose challenges to clinical teaching methodology, while at the same time they offer opportunities for students to learn about complex criminal litigation. In this way, innocence cases share certain characteristics with civil rights and other large-scale litigation projects that are sometimes undertaken in law-school clinical settings.

Undergraduate Education

The formal education mission extends beyond law schools. One of the earliest innocence organizations, the Medill School of Journalism Innocence Project at Northwestern University in Evanston, Illinois, is an undergraduate journalism program in investigative journalism, as are more recently created projects such as the Justice Brandeis Innocence Project at the Schuster Institute for Investigative Journalism at Brandeis University, and the Innocence Institute of Point Park University in Pittsburgh. Still other projects, such as the Northern Arizona Justice Project and the Downstate Illinois Innocence Project, provide educational opportunities for students in other educational programs, such as criminal justice or legal and policy studies.

The Policy Mission

Lessons from the Innocence Cases

A central goal of the innocence movement has been to draw lessons from the wrongful convictions that can lead to reforms to minimize the risk of false convictions. Examining the DNA exonerations in particular has revealed several recurring causes of factual error in criminal cases.

Among the recurring contributors to wrongful convictions, eyewitness error is by far the most prevalent, occurring in 76% of the first 250 DNA exoneration cases. Eyewitness error typically does not involve untruthful witnesses, but rather well-meaning, honest witnesses who are simply mistaken about their memory of the perpetrator or the crime. Considerable psychological research has demonstrated the fallibility of eyewitnesses, and identified factors that can contribute to eyewitness error. Eyewitness memory is susceptible to contamination and distortion by suggestive police identification procedures or postincident information, and may be impaired initially by the conditions under which the crime occurred.

False confessions are also prominent among the causes of wrongful convictions, present in 16% of the first 250 DNA exonerations. Although it is counterintuitive to imagine that an innocent person would confess to a crime he or she did not commit, the DNA exonerations demonstrate the reality of false confessions. High-pressure, confrontational police interrogation tactics, such as those included in the Reid Technique of interrogation (which is taught in some form in most police jurisdictions in the United States), which are believed to be effective at eliciting confessions from the guilty, also can induce innocent people to confess. Social science research suggests that, under such interrogation tactics, false confessions can be the product of rational choices.

Jailhouse informer or ‘snitch’ evidence, present in 21% of the first 250 DNA exonerations, typically involves testimony offered by individuals who are themselves in trouble with the law and claim that the defendant confessed or made incriminating statements to them. Courts have long recognized that such witnesses are very unreliable, both because their criminal background suggests that they might have little regard for the truth and more importantly because they have an incentive to fabricate hopes of obtaining benefits from the state in return.

Numerous wrongful convictions have also rested in part upon fraudulent or mistaken forensic science. Forensic evidence was offered in more than 70% of the first 250 cases in which DNA later exonerated the defendant. According to Brandon Garrett, in those cases with forensic testimony, 61% of the cases involved improper or scientifically unsupported testimony.

Police and prosecutorial misconduct involves overreaching in a variety of contexts. The most common type of prosecutorial misconduct involves failure to comply with the constitutional mandate that prosecutors must disclose to the defense all material exculpatory evidence in their possession. In part, a prosecutor’s failure to comply with this mandate reflects the very difficult demands that the adversary system imposes on prosecutors. For a prosecutor whose responsibility to convict the accused naturally encourages him or her to view the evidence in an inculpatory light, it expects a great deal to require that same prosecutor to simultaneously view the evidence from the defendant’s perspective, and to recognize its exculpatory value.

Finally, inadequate defense counsel is a frequent cause of wrongful convictions. Indigent legal services are chronically underfunded, and the result frequently is inadequate defense investigation and a lackluster challenge to the state’s case at trial. When the defense is inadequate, the adversarial system fails to function as designed to weed out erroneous charges or to protect the innocent.

Preventing and Remediating Wrongful Convictions

Increasing awareness in the criminal justice system of the problem of wrongful convictions has also led to a heightened interest in reforms to reduce the rate of such errors. Policy makers have become interested in reforms to prevent wrongful convictions, not just because each such case is an injustice to the wrongly convicted, but also because they recognize that every time an innocent person is wrongly convicted, the true perpetrator eludes prosecution. A variety of official

commissions and policy-making bodies, sometimes dubbed 'innocence commissions,' have been created in a number of jurisdictions to examine the wrongful conviction cases and develop recommendations for reforms to minimize such errors.

Minimizing eyewitness error

To date, most progress in implementing reforms designed to minimize wrongful convictions has been made in the areas of eyewitness error and false confessions. In particular, extensive psychological research has produced a well-developed series of recommendations for improving eyewitness identification procedures. A number of law enforcement agencies throughout the country are now implementing some or all of these recommendations. Some of these reforms are being adopted voluntarily by law enforcement; in other instances, the reforms are mandated by new statutes or court rulings.

Some of the more significant eyewitness identification reforms include ensuring that witnesses are properly instructed that the perpetrator might not be present in any given lineup or photo array, so that the witness does not feel compelled to pick someone in every case; properly selecting lineup or photo array 'fillers' (nonsuspects) so that the suspect does not stand out; presenting no more than one suspect in any given lineup or photo array; conducting the identification procedure in a 'double blind' manner – meaning that neither the witness nor the detective administering the procedure knows which individual is the suspect – so that the detective cannot even inadvertently cue the witness as to whom to pick; and presenting photographs or lineup members sequentially, rather than simultaneously, so that the witness must rely on absolute judgments drawn from memory, rather than relative judgments based on comparing one lineup member or photograph to the others.

Guarding against false confessions

The most significant reform designed to prevent false confessions is a requirement that all custodial interrogations be electronically recorded from start to finish. Recording serves several purposes. It deters police from engaging in improper coercive tactics or feeding crime-related information that can produce false confessions. It also creates a clear record of what was said and done, so that lawyers, judges, and juries can more fully and accurately consider the reliability of any statements elicited during an interrogation, and indeed help factfinders accurately determine what the suspect said, in their own words, without interpretation or paraphrasing by police witnesses. Electronic recording also protects police from spurious claims of misconduct in the interrogation room, and produces powerful evidence to help convict the guilty when a suspect freely and convincingly confesses or incriminates himself in a recording that can be played for the jury.

Model statutes

On a variety of topics, the Innocence Project has also produced model statutes, and has worked with legislatures around the country to encourage them to adopt them. Model statutes address such matters as

- Requiring states to preserve biological evidence after conviction

- Creating a right to postconviction DNA testing in cases in which test results favorable to the defendant might provide a basis for overturning the conviction
- Improving eyewitness identification procedures
- Mandating electronic recording of custodial interrogations of suspects
- Providing or improving compensation packages available to exonerees
- Creating forensic oversight commissions

Federal legislation

At the federal level, the Innocence Project actively worked to pass the Justice for All Act of 2004, which President George W. Bush signed into law on 30 October 2004. That Act includes the Innocence Protection Act, which, among other things, grants federal inmates the right to petition a federal court for DNA testing to support a claim of innocence and encourages states – through the power of the purse – to adopt measures to preserve evidence and make postconviction DNA testing available to inmates seeking to prove their innocence. The Justice for All Act also includes provisions that assist death-penalty states with efforts to create effective systems for the appointment and performance of qualified counsel, together with better training and monitoring for both the defense and prosecution. It provides substantial funding to states for increased reliance on DNA testing in new criminal investigations, increases the amount of compensation available to wrongfully convicted federal prisoners, and expresses the idea of Congress that all wrongfully convicted persons should be reasonably compensated.

In 2009, the National Academy of Sciences (NAS), the preeminent scientific authority in the United States, issued a groundbreaking report on the status of forensic sciences in the United States. The NAS concluded that the forensic science system in the United States is in disarray – fragmented, inadequately regulated, and poorly grounded in science. Central to its call for reform was its recommendation that the federal government create a National Institute of Forensic Sciences to encourage research, provide oversight, and establish standards for forensic science evidence in the United States. The Innocence Project has since then been actively involved in efforts to implement this and the other recommendations of the NAS.

Amicus briefs

Finally, the Innocence Network and its member projects have become active, through the Network's Committee on Amici and Policies, in producing amicus briefs in state and federal litigation on issues related to wrongful convictions. Numerous Innocence Network and individual project briefs have been filed in the United States Supreme Court, many federal circuit courts of appeals, and various state supreme courts, and intermediate appellate courts. Innocence Network briefs are frequently cited in decisions by these courts, and have been influential in numerous court decisions.

Glossary

ABO blood typing A commonly used genetic typing test that uses antibodies to detect variations on the surface of human blood cells. Individuals are typed as having A, B, O, or AB blood types.

CODIS Combined DNA Index System, established by the FBI, composed of a collection of databases of DNA profiles obtained from evidence samples from unsolved crimes and known convicted offenders.

Mitochondrial DNA The DNA found in the many mitochondria found in each cell of a body. Mitochondrial DNA (mtDNA) can be used to obtain profiles from cells that have no nucleus, such as cells in hair shafts, or in degraded samples. The sequencing of mtDNA can link individuals descended from a common female ancestor.

Polymerase chain reaction (PCR) A process used in DNA identification testing in which one or more specific small regions of the DNA are copied using a DNA polymerase enzyme so that a sufficient amount of DNA is generated to permit analysis.

Restriction fragment length polymorphism (RFLP) A process used primarily in the late 1980s and early 1990s for DNA identification testing involving measuring size (fragment length) differences at specific regions of the DNA.

Short tandem repeats (STR) Small regions of DNA that contain short segments of repeating patterns of base pairs. Thirteen STR sequences have been selected for the Combined DNA Index System (CODIS).

Discovery of Wrongful Convictions Through DNA Testing

Until the early 1990s, the common wisdom in the United States was that the criminal justice system rarely, if ever, wrongly convicted innocent people. That sentiment was expressed perhaps most famously by Judge Learned Hand, who wrote in 1923 that “[o]ur procedure has been always haunted by the ghost of the innocent man convicted. It is an unreal dream.” A few years later, a prosecutor in Worcester County, Massachusetts, declared, “Innocent men are never convicted. Don’t worry about it. It is a physical impossibility.” More recently, former Attorney General Edwin Meese quipped, “But the thing is, you don’t have many suspects who are innocent of a crime. That’s contradictory. If a person is innocent of crime, then he is not a suspect.”

DNA has changed that perception and, in the process, has reshaped the debate about criminal justice in America. As of July 2012, 292 people had been proven innocent of serious crimes – mostly rapes and murders – by DNA testing conducted years, and sometimes decades, after they were wrongly convicted and sentenced to prison or even to death. The DNA exonerations, by creating an awareness of the fallibility of the system, have also led to hundreds of other successful efforts to exonerate individuals even where there is no DNA evidence.

Moreover, by demonstrating the reality of error in the criminal justice system with scientific certainty, the DNA exonerations created a learning opportunity – an opportunity to study the wrongful convictions and identify sources of error that can be avoided in the future. As a consequence, the DNA exonerations have led to a host of reforms intended to improve the reliability of the criminal justice system in its core function – sorting the guilty from the innocent. Those reform proposals – some of which have been adopted in various jurisdictions – typically focus on eyewitness identification procedures, electronic

recording of interrogations to reduce false confessions, improved reliability and oversight of the forensic sciences, limitations on unreliable jailhouse informant testimony, and improved indigent defense services, among others.

Emergence of DNA as a Forensic Tool

In 1984, geneticist Sir Alec Jeffreys, working in his laboratory in Leicester, England, developed the first forensic DNA profiling technology, utilizing multilocus probes and a method known as restriction fragment length polymorphism (RFLP) analysis. Jeffreys dubbed this new forensic DNA technique ‘DNA fingerprinting.’ The age of forensic DNA technology was born.

The First Exoneration: The Pitchfork Case

The first forensic application of Jeffreys’s new DNA technology simultaneously produced a conviction and an exoneration. In November 1983, the body of a raped and strangled 15-year-old girl was found lying near a footpath in the village of Narborough, England, not far from Leicester. At the time of the Narborough crime, the forensic science in such cases was standard ABO blood group analysis, or serology testing. Serology testing determined that semen recovered from the girl’s body was from a type A secretor with enzyme marker PGM1+. That serology profile limited the possible sources to 10% of the adult male population. But that was all police had; they had no suspects and no leads.

Three years later, in 1986, the body of another 15-year-old girl – who had also been raped and strangled – was found in the adjoining village of Enderby, within a mile of the first rape site. As in the first case, serology analysis determined that the perpetrator was a type A, PGM1+ secretor.

This time, though, police had a suspect, a 17-year-old kitchen porter at a nearby mental hospital. The boy, who was known to be mentally slow, confessed to the second murder, but refused to confess to the first. But there was a problem: the boy was not a PGM1+ secretor. Despite the serology exclusion, the boy remained the prime suspect; the serology evidence alone was not enough to overcome the power of the confession.

Without a confession in the first case, but suspecting the boy of both crimes, police called in Dr. Jeffreys to analyze the old semen sample from the first rape/murder to see if it matched the DNA from a blood sample from the accused boy. Using a single-locus probe, Jeffreys excluded the suspect. Police then sent Jeffreys the semen sample from second murder. Again, the DNA excluded the suspect. Moreover, the DNA from the second case matched the sample from the first case. The two crimes had an apparent common perpetrator, but it was not the accused boy. Finally, police accepted the boy's innocence and released him. The world had its first DNA exoneration.

Police then sought to use the new DNA technology aggressively to solve the crime. They asked all male residents of Narborough and Enderby between the ages of 17 and 34 to supply blood and saliva samples voluntarily for analysis. Police collected nearly 5000 samples. Five hundred of those men could not be eliminated by conventional serology testing, so their samples were subjected to DNA analysis. Initially, no one matched. But police soon learned that a baker named Colin Pitchfork had convinced a fellow employee to provide blood and saliva samples in place of his own. When confronted with evidence of this deception, Pitchfork confessed and pled guilty and, subsequently, received concurrent life sentences for the two crimes. The DNA had both exonerated the wrongly accused and convicted the guilty.

The Growth of DNA Exonerations

In the late 1980s, prosecutors began to use the new technology extensively to match crime scene evidence to suspects. Soon, the defense began to realize the potential for DNA evidence to prove innocence as well.

Discovering innocents in prison

In 1989, in Illinois, Gary Dotson became the first person exonerated by DNA evidence after being wrongly convicted. Twelve years earlier, in 1977, a young woman claimed that two men had abducted her as she walked home from work, forced her into the back seat of a car, and raped her. In 1979, Dotson was convicted of aggravated kidnapping and rape of the woman and sentenced to 25–50 years in prison. The evidence against him included the victim's eyewitness identification; serology testing that revealed that swabs with semen from the rape kit included both blood groups type A and type B and that both the victim and Dotson were type B, thereby purportedly including Dotson (although it should have meant that Dotson was excluded as the source of the semen, since neither he nor the victim could have contributed the type A secretions); and forensic testimony that a pubic hair recovered from the victim's underwear was dissimilar to the victim's hair but similar to Dotson's.

In 1985, 6 years after Dotson's conviction, the victim confessed that she had fabricated the rape to hide a consensual sexual encounter with her boyfriend. The Illinois courts and governor rebuffed the victim's recantation and refused to vacate the conviction (although the governor commuted the sentence). In 1987, Dotson's lawyers asked Dr. Jeffreys for RFLP analysis, but the samples were too badly degraded to produce conclusive results. Dotson's lawyers then sent the samples to Dr. Edward Blake at Forensic Science Associates in Richmond, California, to apply another more sensitive but less discriminating technology – polymerase chain reaction (PCR) DQ Alpha testing. Those tests revealed that the sperm on the victim's underwear could not have come from Dotson but could have come from the victim's boyfriend. Dotson's conviction was vacated, and the charges were dismissed.

A second DNA exoneration followed in late 1989. Another followed a year later in 1990, and then two more in 1991. More exonerations followed swiftly thereafter, and in increasing numbers in ensuing years.

New technologies

New technologies that made testing increasingly feasible soon emerged, even with minute or degraded samples. PCR, a process roughly analogous to DNA xeroxing, combined with short tandem repeat (STR) analysis replaced RFLP as the dominant technology and enhanced both the sensitivity and discriminating power of DNA analysis. PCR/STR testing, for example, permitted analysts to obtain DNA profiles from some objects that a perpetrator merely touched (often referred to as 'touch DNA' or 'contact DNA'). At the same time, mitochondrial DNA testing (mtDNA) permitted analysis of DNA from non-nucleated cells, such as those in the shafts of hairs, and from degraded samples. Y-STR testing permitted profiling only the DNA from the male portions of a mixture, an important step in identifying small amounts of male DNA that might otherwise be masked or overwhelmed by female DNA in a vaginal swab. Other emerging technologies continue to expand the power of DNA testing.

Databasing

Development of the FBI database of DNA profiles also enhanced the ability of the criminal justice system both to identify the guilty and exonerate the innocent. The FBI database – the Combined DNA Index System (CODIS) – is a collection of databases of DNA profiles obtained from evidence samples from unsolved crimes and from offenders convicted of particular crimes. CODIS has been critical in exonerating innocent people from cases where an exclusion from the crime scene evidence might not alone be enough to prove innocence.

Chaunte Ott, for example, convicted of a brutal murder of a young woman in Milwaukee, Wisconsin, would not have been exonerated but for a match in the database. Ott was convicted of murder but not sexual assault. So when DNA from the victim's vaginal swabs produced a male profile that did not match Ott, it was not enough to exonerate him; the state contended that the semen was unrelated to the crime and must have come from a prior consensual encounter. But years later, when the profile from that rape kit produced CODIS matches to DNA from the rape kits from two other women who had also been murdered in the same part of Milwaukee and in the

same time period, it became apparent that the DNA was not irrelevant to the crime. That conclusion was confirmed when subsequent CODIS matches linked the DNA to a total of nine women who had been raped and murdered by a man named Walter Ellis, who became known as Milwaukee's infamous North Side Strangler. With this link to a serial killer, Ott was exonerated, freed, and compensated for his years of wrongful imprisonment.

Impact on the System

By 1996, the exonerations began to have an impact on the law enforcement and judicial communities. In that year, the United States Department of Justice, through the National Institute of Justice (NIJ) and at the direction of then Attorney General Janet Reno, published a research report examining the first 28 DNA exonerations of wrongly convicted individuals. Reflecting the reality that rape tends to produce significant biological evidence from the attacker, all 28 of these first cases involved sexual assault; in 6 of the cases, the victim was also murdered. The 28 defendants had served a total of 197 years in prison – with an average of almost 7 years each – before being exonerated by DNA.

In response to the NIJ report, Attorney General Reno asked the NIJ to establish a National Commission on the Future of DNA Evidence to identify ways to maximize the value of DNA in the criminal justice system. In September 1999, the Commission published a report entitled *Postconviction DNA Testing: Recommendations for Handling Requests*. In that report, the Commission encouraged prosecutors and defense attorneys to cooperate on arranging postconviction DNA testing in cases where it might exonerate the defendant.

Preservation of and Access to DNA Evidence

The success of DNA as a tool to exonerate the wrongly convicted highlighted a problem with the existing system for evaluating such evidence: no rules in most states required the government to preserve biological evidence after conviction so that it would be available for future testing, and most states provided no right or mechanism for accessing such evidence for postconviction DNA testing. Beginning first in Illinois and New York, states began passing legislation providing a right to postconviction DNA testing when it might prove innocence. Other states and the federal government soon followed. Many also required preservation of biological evidence after conviction. Today, most states and the federal government require preservation, and 49 states, the federal government, and the District of Columbia provide a statutory right of access to evidence for postconviction DNA testing when it might prove innocence, although some are limited to certain offenses or time periods; only Oklahoma has yet to adopt any postconviction testing statute.

In those jurisdictions where there was no postconviction DNA testing statute, or where the statutes were for any reason inadequate, imprisoned individuals turned to another source for a right to the testing: the courts and the Due Process Clause of the Constitution. Under federal civil rights law (42 U.S.C. sec 1983), prisoners sued the states claiming that denying them access to the DNA evidence violated their due process rights.

A number of courts granted relief in such cases, and some produced exonerations.

In 2009, however, in *District Attorney's Office for the Third Judicial District v. Osborne*, 129 S.Ct. 2308 (2009), the court found no due process right to testing where state law already provided an adequate opportunity to secure the test. *Osborne* recognized that state law can indeed create a due process liberty interest in accessing DNA evidence that can prove innocence. A question that remains open is how the court will assess claims that a state law does not adequately protect the opportunity for testing.

DNA Exonerations Today

The Exonerations

As of July 2012, the total number of known DNA exonerations of wrongly convicted individuals had risen to 292. As the number of innocence projects in the United States grew each year, the technology advanced and awareness of the problem of wrongful convictions increased; the number of exonerations grew steadily after 1992, peaking at 25 exonerations in 2002. Despite predictions that the rate of postconviction DNA exonerations would begin to dwindle as DNA testing was completed on most old cases, the number of exonerations each year has remained fairly constant since then, ranging between 13 (in 2004) and 23 (in 2009). The number of exonerations per year is set forth in [Table 1](#).

Analysing the first 250 of these DNA exonerations, Professor Brandon Garrett found that these innocent men and women spent an average of 13 years in prison. Seventeen had been sentenced to death, and 80 were sentenced to life in prison. Approximately 98% of the 250 innocent people had been convicted of rape or rape and murder. The overrepresentation

Table 1 DNA exonerations by year

2010	18
2011	15

of rapes and murders among these cases could reflect a higher-than-normal error rate in such cases, given the intense public pressure on police and prosecutors to obtain a conviction in such high-profile cases. More likely, the primary reason the DNA exonerations include almost entirely rapes and rape/murders is that sexual assaults are the crimes most likely to yield biological evidence for DNA analysis. That explanation would suggest that there might be untold numbers of individuals convicted of other crimes who are also innocent and wrongly convicted but are unable to obtain vindication through DNA testing because the cases lack testable biological evidence.

Of those exonerated by DNA, 70% were minorities. In rape cases, 75% of the exonerees were black or Latino, while only 30–40% of all rapes are committed by minorities. Most rapes are committed within racial groups; 90% are committed by offenders of the same race as the victim. Yet among exonerees, nearly half of all wrongful rape convictions involved black or Latino perpetrators and white victims.

The DNA evidence in many of these cases did more than exonerate an innocent person. In 45% of the DNA exonerations, the DNA tests identified the actual rapists or murderers, many of whom had been free for years and had gone on to commit other crimes, while an innocent person sat in prison for their crimes.

Features of Wrongful Convictions

Study of the DNA exonerations has provided insights into the types of evidence and errors that create false convictions.

Eyewitness error

The most prevalent type of erroneous evidence in these cases is eyewitness error; eyewitnesses wrongly identified the accused in 76% of the first 250 cases. Typically, these eyewitnesses misidentified an innocent person not because they were lying but because they were simply mistaken. Considerable research has now confirmed the fallibility of eyewitness memory and identified police practices that can even unintentionally taint an eyewitness's memory and produce false identifications. Indeed, Garrett's review of the first 250 DNA exonerations found that in 78% of the cases, police contaminated the eyewitness identifications with suggestive methods, like giving cues – whether intentionally or not – about which lineup member was the suspect or conducting lineups where one suspect obviously stood out from the others.

Reforms to improve eyewitness accuracy are beginning to emerge from the new recognition about the seriousness of the eyewitness error problem. Many states, including New Jersey, North Carolina, Ohio, and Wisconsin, among others, are implementing social-science-based police practices designed to minimize eyewitness error. These reforms include practices like instructing eyewitnesses before an identification procedure that the real perpetrator might or might not be present, as the witness should not feel compelled to pick someone; ensuring that everyone included in a lineup or photo array fits the description of the perpetrator, so that no one stands out; conducting lineups and photo arrays in a 'blind' manner, meaning that the police officer administering the test does not know which person is the suspect; presenting suspects and fillers (known innocent individuals included in the procedure to fill

out the lineup or photo array) to the witness sequentially rather than simultaneously, so as to minimize the tendency to compare faces and pick the best fit, rather than only picking an individual truly recognized as the perpetrator; including only one suspect per identification procedure; presenting any one suspect to a witness only once, rather than in several repeated procedures; and accurately recording a witness's statement of confidence immediately after making an identification, before the witness receives any confirming or disconfirming feedback about his or her 'pick.'

Flawed forensic science evidence

Based on Garrett's study, the second most prevalent type of evidence in the first 250 DNA exonerations is forensic science evidence. Seventy-four percent of the DNA exonerations included other forensic science evidence. The forensic evidence in these cases included serology testing (as in Pitchfork and Dotson) (116 cases), microscopic hair comparison (75 cases), fingerprints (20 cases), bite mark comparison (7 cases), shoe print comparison (6 cases), and voice comparison (1 case). Brandon Garrett and Peter Neufeld have analyzed the transcripts of the testimony of forensic analysts in 153 of the DNA exoneration cases in which transcripts are available and found that the forensic testimony was invalid in 61% of the cases, either by misusing population data or by drawing conclusions unsupported by empirical data as to the probative value of the evidence. In the remaining cases, the science might have been valid but of limited utility when compared to DNA's greater ability to discriminate. Forensic testimony was invalid in virtually every category of forensic science, including 58% of the serology testimony, 39% of the hair comparison testimony, 71% of the bite mark testimony, 17% of the shoe comparison testimony, and 5% of the fingerprint testimony.

Some of these techniques, such as microscopic hair analysis, are not in wide use any longer, but the methodologies and types of testimony that went awry in these cases continue today in a variety of forensic disciplines. A landmark study by the National Academy of Sciences (NAS) carefully examined the state of forensic sciences and concluded, "With the exception of nuclear DNA analysis, . . . no forensic method has been rigorously shown to have the capacity to consistently, and with a high degree of certainty, demonstrate a connection between evidence and a specific individual or source." Indeed, the NAS concluded that – again excluding DNA – "[l]ittle rigorous research has been done to validate the basic premises and techniques in a number of forensic science disciplines."

False confessions

Counterintuitively, the DNA exonerations establish that innocent people do confess to serious crimes like rapes and murders that they did not commit. Of the first 250 DNA exonerations, 16% involved false confessions. In homicides, where there is usually no surviving victim eyewitness and hence confessions become more critical to police, approximately two-thirds of the DNA exonerations involved false confessions. Almost all these false confessions included significant details of the crimes, including details not publicly known, which the police routinely claimed they had not disclosed to the suspect and that only the true perpetrator would have known. Yet research reveals

that in fact, most of these confessions were contaminated by police and produced by intense interrogation tactics in prolonged interrogations that lasted hours, or even days, utilizing psychological tactics to convince the suspect to confess.

Courts, legislatures, and police departments have found that the most important first step in addressing the problem of false confessions is to require that all custodial interrogations of suspects should be electronically recorded, from start to finish, and without interruption. Such recordings protect suspects from coercive tactics and make a record when police go too far or when they contaminate the interrogations with supposedly secret crime details. At the same time, electronic recording protects police from spurious claims of misconduct in the interrogation room. Recordings of voluntary confessions also provide prosecutors with powerful evidence of guilt. To date, police in 11 states and the District of Columbia are required or encouraged to record at least some interrogations, and police in hundreds of jurisdictions around the country have begun to record voluntarily.

False informant testimony

Twenty-one percent of the first 250 DNA exonerations had informant testimony at the defendant's initial trial. Most of this testimony was provided by jailhouse informants, codefendants, or confidential informants or cooperating witnesses. These witnesses typically testified that the defendants confessed the crime to them and provided details about how they committed the crime. The criminal justice system has long known that such witnesses lack credibility because they have an incentive to fabricate evidence against the defendant, yet the system has simultaneously approved reliance on informant testimony. Potential informants know, or hope, that providing such evidence to the state will produce leniency or other benefits in their own cases. Yet the system does little to protect against such false testimony. The DNA exonerations confirm the seriousness of the threat that such testimony poses to accurate fact finding at trial and has led to some proposals for reform or greater scrutiny of such proof.

Other features of the wrongful convictions

Other common features of the wrongful convictions exposed by postconviction DNA testing include various forms of police and prosecutorial misconduct and inadequate or ineffective representation by defense counsel. Additionally, virtually every case exhibits some degree of tunnel vision – the combination of innate cognitive biases (e.g., confirmation bias and outcome bias) and institutional pressures that predispose investigators to focus on a suspect and then filter all subsequent information in the case through the lens of that early conclusion about the suspect's guilt.

Finally, the DNA exonerations tell a story of appellate failure. Very few of these innocent defendants obtained relief during the appellate review of their convictions. Most courts affirmed the convictions of these innocent defendants, and in approximately half the cases, courts commented on the strength of the evidence of guilt, while in 10% of the cases, the appellate courts called the evidence of the innocent person's guilt 'overwhelming.'

Expert Witness Qualifications and Testimony

C Henderson, Stetson University College of Law, Gulfport, FL, USA
KW Lenz Esq., Saint Petersburg, FL, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The field of scientific interpretation of evidence and its portrayal in popular media has progressed to the point that expert testimony at trial is not only commonly accepted by judge and jury, but also expected. This article addresses the factors that influence the selection of an expert, including the importance of investigating the expert's credentials and making an informed assessment of the credibility that the expert's qualifications will project to a judge and jurors.

Although this article is written from a US perspective, many of the issues discussed here are applicable to expert witness testimony worldwide. This article will not, however, address the legal standards for the admissibility of expert testimony or attorneys' ethics in dealing with experts.

Selecting an Expert

Many variables should be considered in selecting an expert witness, including the expert's availability, cost, experience, and reputation. When an expert serves as a consultant or in the pretrial phases of litigation, the criteria for selecting that expert may be limited to the expert's competency in the field. As a trial witness, however, the expert's integrity, charisma, and overall effectiveness as a witness must also be considered.

Thus, consideration should be given not only to the expert's formal training but also to the expert's personality, demeanor, and capacity to organize, express, and interpret complex concepts for the jury. The weight accorded to the expert's opinion by the judge or jury will be determined in large part by the expert's perceived character, objectivity, and impartiality.

Of course, the quality of the expert's credentials remains an important factor to consider as well. A thorough evaluation of an expert should take into account matters such as (1) the membership requirements of the associations to which the expert belongs, (2) how the expert's credentials compare to those of the opposing expert, (3) whether the journals in which the expert's articles appear are held in high regard in the field, and (4) whether the conclusions in those articles were subject to peer review. Studies of jurors' perceptions of experts can be particularly helpful in guiding this evaluation.

Care should always be taken to verify the credentials of one's own expert, as well as those of an adversary's expert, for although it is unlikely that an expert has faked credentials, it has occurred. Indeed, experts have come under increased scrutiny in recent years for fabricating or inflating their qualifications.

Qualifications

The court must determine whether a proffered witness is qualified to testify as an expert, and that determination will not be

overturned except for an abuse of discretion (*Kumho Tire Co. Ltd. v. Carmichael*); but see, for example, *Radlein v. Holiday Inns, Inc.* (holding that the trial court's decision will not be reversed unless there is a clear showing of error). Federal Rule of Evidence 702 states that a witness may qualify as an expert on the basis of knowledge, skill, training, experience, or education. An expert witness must possess only one of these traits for the judge to find the expert qualified to give an opinion. In making this evaluation, the judge may consider the expert's educational background, work experience, publications, awards, teaching, speaking, or other professional engagements, prior expert-witness testimony, and membership in professional associations.

Often, the expert may have to educate the attorney proffering the expert regarding the significance of particular experience, achievements, and certifications to ensure that they are appropriately presented to the judge. An expert must be prepared to explain board certification and licensure requirements to the judge in detail.

Experience as an Expert Witness

Experience and training are often more significant than academic background and are accorded more weight by jurors, according to at least one study evaluating juror perceptions of fingerprint experts. However, experience as an expert witness, standing alone, does not qualify someone as an expert in later cases. One court rejected the opinion of a witness who had testified as an expert 126 times (*Bogosian v. Mercedes-Benz of North America Inc.*). Another court noted that, "it would be absurd to conclude that one can become an expert by accumulating experience in testifying" (*Thomas J. Kline, Inc. v. Lonillard, Inc.*). Conversely, a lack of previous experience as an expert witness does not disqualify one from testifying as an expert, because "even the most qualified expert must have his first day in court" (*US v. Locascio*).

Education and Training

An expert may be qualified on the basis of academic credentials, including the expert's undergraduate, graduate, and post-graduate work. An expert's academic credentials should only be issued by accredited educational institutions and programs, because the proliferation of the Internet, while laudable for so many reasons, has also rekindled the old-fashioned diploma mill. One such business, Diplomas 4U, once provided bachelor's, master's, MBA, or PhD degrees in its customers' field of choice; advertisements assured that no one would be turned down and that there would be no bothersome tests, classes, books, or interviews. After studying this issue, the

National Academy of Sciences has concluded that it is crucially important to improve undergraduate and graduate forensic science programs with, among other things, attractive scholarship and fellowship offerings, and funding for research programs to attract research universities and students in fields relevant to forensic science.

An expert should continuously perform research and publish in the expert's field, preferably in peer-reviewed publications. Teaching experience is another of the qualifications that judges will evaluate: all forms of teaching – regular, specialty, guest lecturing, visiting professorships, continuing education, and short courses – weigh in as credentials. An expert should also be up to date with developments in his or her field of expertise by reading the current literature, enrolling in continuing education seminars, joining professional societies, and attending professional meetings.

Membership in Professional Associations

A study published by the US Department of Justice in 1987 found that jurors perceived those fingerprint experts who belonged to professional associations to be more credible than other experts, and presumed experts would belong to such groups (Illsley, *supra*). It is therefore important for an expert to remain active and participate in professional societies; the expert's credibility is diminished if the expert has not recently attended a professional meeting. Professional associations that only require annual dues payment to become a member are not as prestigious as associations that are joined by special invitation only, by approval of special referees, or by passing an examination.

Thus, an expert should be selective about which professional associations to join. The NAS Report calls for standardized accreditation and/or certification, as well as a uniform code of ethics:

Although some areas of the forensic science disciplines have made notable efforts to achieve standardization and best practices, most disciplines still lack any consistent structure for the enforcement of 'better practices,' operating standards, and certification and accreditation programs Accreditation is required in only three states . . . [and] [i]n other states, accreditation is voluntary, as is individual certification. . . . NAS Report at 213

Thus, the NAS Report calls for the creation of a federal agency to develop tools to advance reliability in forensic science, to ensure standards that reflect best practices, and serve as accreditation tools for laboratories and as guides for the education, training, and certification of professionals (NAS Report at 214).

Increased Scrutiny of Experts

Experts have come under increased scrutiny for either fabricating or inflating their qualifications. In Florida, in 1998, a person who had been testifying as an expert in toxicology for 3 years for both the prosecution and defense in criminal cases was prosecuted for perjury for testifying with fraudulent credentials. The expert claimed to possess master's and doctorate

degrees from Florida Atlantic University, but when a prosecutor sought to confirm the claims, he discovered that the registrar's office had no record of the expert attending or receiving a degree from the university.

In another case, a Harvard medical professor was sued for trademark infringement for falsely claiming to be board-certified by the American Board of Psychiatry and Neurology (ABPN) in five trials (*ABPN v. Johnson-Powell*). The board sought to seize the expert's witness fees and treble damages, but the court denied that relief because it believed the expert was unlikely to infringe in the future.

In 2007, a court granted the plaintiff a new trial in her product liability action when it was discovered that the pharmaceutical company's cardiology expert had misrepresented his credentials by testifying that he was board-certified in internal medicine and cardiovascular disease when in fact those certifications had expired (*In re Vioxx Products*).

In addition to perjury prosecutions for false qualifications, some jurisdictions also prosecute for academic fraud. For example, in Florida, a person who misrepresents association with, or academic standing at, a postsecondary educational institution is guilty of a first-degree misdemeanor (Fla. Stat. § 817.566).

Courts have also overturned convictions where the experts testified outside their field of expertise. Instances include a medical examiner testifying to shoe-pattern analysis and an evidence technician with no ballistics expertise giving testimony about bullet trajectory (see *Gilliam v. State*; *Kelvin v. State*).

There is evidence to suggest that, since the Supreme Court's decisions in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, and *Kuhmo Tire Co.*, courts have been more willing to exclude expert testimony. The Federal Judicial Center compared a 1998 survey of 303 federal judges with a 1991 survey. In 1998, 41% of the judges claimed to have excluded expert testimony, whereas only 25% of the judges did so in 1991. A 2001 RAND study similarly concluded that judges were becoming more vigilant gatekeepers; for example, in the US Third Circuit Court of Appeals, the exclusion rate in products liability cases rose from 53 to 70%. This contradicts most of the reported case law following *Daubert*, which seems to indicate that the exclusion of expert testimony remains the exception, not the rule. (see Fed. R. Evid. 702).

Weight of the Evidence

Once a judge decides that an expert may testify, the jury must then decide the weight to accord the expert's opinion. Jurors have become familiar with the role of the expert witness at trial through the coverage of high-profile cases in the popular media and fictional television depictions such as 'CSI'. Studies have shown that jurors have increased expectations for scientific evidence, and that in cases based on circumstantial evidence, jurors are more likely to acquit a defendant if the government did not provide some form of scientific evidence. Expert witnesses and attorneys should be aware of studies regarding jurors' perceptions of expert witnesses and how those perceptions have evolved over time.

For example, a 1994 study revealed that the characteristics of experts that were most important to jurors in determining

the experts' credibility were (1) the expert's willingness to draw firm conclusions and (2) the expert's ability to convey technical information in plain language that a layperson could understand. Another study concluded that an expert's believability is linked to the expert's qualifications, familiarity with the facts of the case, good reasoning, and perceived impartiality. Jurors were also influenced by independent research that corresponded with the expert's opinion.

A 1998 study exposed jurors as a more skeptical, cynical group. Among the findings, the study concluded that 50% of those surveyed thought that expert witnesses say only what they are paid to say; 33% did not believe police testimony; and 75% said they would set aside what a judge says the law requires and reach a verdict the jurors felt was right. Yet another study concluded that using expert testimony to counter the prosecution's expert in criminal cases caused jurors to be skeptical of all expert testimony, rather than simply sensitizing them to flaws in the prosecution expert's testimony. In fact, jurors rendered more guilty verdicts when they heard defense expert testimony than when they did not. This study throws into question the Supreme Court's assumption in *Daubert* that opposing expert testimony effectively safeguards against 'junk' science in the courtroom.

Increasing awareness of errant experts and exonerations of the wrongly accused has influenced how jurors perceive scientific evidence. For example, background beliefs about the possibility of laboratory errors and intentional tampering affect the weight jurors afford a DNA report, and jurors with such beliefs gave probability estimates less weight. A separate poll regarding forensic fraud and its impact on potential jurors found that 32% think wrongful convictions happen frequently and 23% said that wrongful convictions are rarely an accident.

Experts must understand that effective communication with jurors requires organized content, and the effective use of visual presentation techniques including, whenever possible, demonstrative exhibits that incorporate large, user-friendly data presentation monitors and systems for use both by the court and by individual jurors, as well as interactive electronic timelines and e-documents that allow jurors to feel they are in control of and have access to all information regarding the facts of the trial. Data also suggest that when testifying to jurors, experts should attempt to associate themselves with a more collaborative, personalized role such as a teacher, rather than a more hierarchal and impersonal profession such as a scientist. Surveys confirm these conclusions distinguishing jurors from generations X and Y from past generations. For example, while 64% of jurors overall believe that the police tell the truth when they testify, only 51% of jurors aged 18–24 years old share that belief; 60% overall and 72% of those aged 18–25 viewed presentations using videos, simulations, and computers positively.

Conclusion

Expert testimony will continue to play an important role in the future. Expert witnesses have been facing increased scrutiny in

the US and worldwide. For more effective expert testimony, lawyers and experts must be aware of the factors that the courts will evaluate in order to determine whether an expert is qualified or not, as well as jurors' changing perceptions of experts.

Forensic Laboratory Reports

J Epstein, Widener University School of Law, Wilmington, DE, USA

© 2013 Elsevier Ltd. All rights reserved.

There is no precise formula, dictated by law or science, as to what a forensic laboratory report must contain when it reports test results or analysis outcomes. Its content may be determined by the individual examiner's predilections, internal laboratory policy, the law of the jurisdiction, accreditation organization standards, or the reason(s) for its production. What can be said with certainty is that by understanding the current criticism of the practice of producing forensic laboratory reports and trends in standards for reports, and by considering the use to which the report may be put in the court process and the legal and ethical commands regarding reporting and, more generally, the duties of the forensic scientist, a model for forensic laboratory reports can be identified.

Before discussing these factors, it bears mention that the term 'report' itself lacks clarity, as it may refer to the complete case file documenting the examination or just to the compilation of results. For this article, the term 'report' denotes the latter – the document prepared for the consumer [the investigator, counsel, or court official who directed that the examination and testing be conducted]. Even this report may vary in degree of detail, as there can be the summary report advising the requesting party of the outcome; a more formal report prepared for disclosure to the court or opposing counsel as part of pretrial discovery; an amplification of the initial discovery-generated report when it is determined that the expert will in fact testify; and a report that will be presented in lieu of actual testimony. Additional documentation may include an administrative or dispositional report detailing the receipt or return of the item(s) sent for analysis.

What must also be acknowledged is that the expert's role in the adjudicative process is in some ways defined by whether the system is adversarial, with the expert being called by the party seeking to establish a point, as in the United States; or inquisitorial/'common law,' where the expert is a court witness, presumed to be neutral, and without allegiance to a particular party, as in France, Belgium, and Germany. These demarcations are not always adhered to, as American law permits a trial judge to appoint and take testimony from a 'court' expert under Federal Rule of Evidence 706, and in some cases involving offenses of fraud and falsification, France permits competing experts. These differing roles, however, do not alter the necessary components of a forensic laboratory report (and, as is detailed below), both ethical and legal considerations as well as a commitment to the role of science may require the report to be neutral and to acknowledge any limitations and/or weaknesses.

Contents of a Report – A 'Science' Standard

At least in the United States, there has been substantial criticism of forensic laboratory reporting. This is found in *Strengthening Forensic Science: A Path Forward*, the 2009 report of the National Research Council of the National Academy of

Sciences. After reporting that forensic laboratory reports lack precise terminology, it concluded that most laboratory reports do not meet the standard it proposed:

As a general matter, laboratory reports generated as the result of a scientific analysis should be complete and thorough. They should describe, at a minimum, methods and materials, procedures, results, and conclusions, and they should identify, as appropriate, the sources of uncertainty in the procedures and conclusions along with estimates of their scale (to indicate the level of confidence in the results). Although it is not appropriate and practicable to provide as much detail as might be expected in a research paper, sufficient content should be provided to allow the nonscientist reader to understand what has been done and permit informed and unbiased scrutiny of the conclusion.

This criticism does not stand in isolation. A 2011 British court decision also expressed concern over the sufficiency of detail and documentation in a forensic [latent print] prosecution. After noting the failure of the examiner to contemporaneously record "detailed notes of his examination and the reasons for his conclusions[.]" the court added that [t]he quality of the reports provided by the Nottinghamshire Fingerprint Bureau for the trial reflected standards that existed in other areas of forensic science some years ago, and not the vastly improved standards expected in contemporary forensic science.

The NRC standard is more detailed than that of various forensic organizations. ASCLD/LAB, for example, requires that only written reports be generated for 'all analytical work' and must contain conclusions and opinions and a clear communication of 'the significance of associations made. ...'

Other standards address the need for full documentation, but do not distinguish between a laboratory's bench notes and the final product. For example, International Organization for Standardization's ISO/IEC Standard 5.10.5 requires that "the laboratory shall document the basis upon which the opinions and interpretations have been made" without specifying where that information is to be recorded. Similar language is used for ballistics reports, as recommended by the Scientific Working Group on firearms [SWGUN] requiring that "[w]hen opinions and interpretations are included, the laboratory shall document the basis upon which the opinions and interpretations have been made. Opinions and interpretations shall be clearly marked as such in the test report."

Yet, the more detailed mandate urged by the NRC Report is not unique. Scholars and agencies have articulated similar or at least substantial standards. A publication of *The Royal Society of Chemistry* in 2004, suggested the following information as appropriate for inclusion in an expert report:

- A summary of the event to contextualize the scientific test(s);
- An outline of the scientific work conducted;
- A listing of items examined;
- Description of the work performed;
- A statement interpreting the findings; and
- An overall conclusion.

The RSC text also urges that the report identify the assistants in the testing and the role each played and include appendices with tables or similar displays of test results.

For DNA analysis, the Federal Bureau of Investigation's standards for DNA laboratories require reports to include a description of the evidence examined and of the technology, results and/or conclusions, and a 'quantitative or qualitative interpretative statement.'

One final scientific issue regarding the contents of a report is the concern over bias. Research has shown that information received by the analyst might affect his/her judgment, as when the examiner receives domain-irrelevant information such as the fact that the suspect whose fingerprints are being examined 'confessed to the crime' or when the verification is not 'blind.' Documentation of such information in a laboratory report (or the bench notes) is one responsive action, as is an internal laboratory policy to reduce analyst or verifier exposure to potentially biasing information.

Contents of Report: Legal Standards

That which science requires is to some extent mirrored in legal requirements for expert reports. These vary from nation to nation, and within nations when states or regions have their own authority to legislate criminal practice.

In the United Kingdom, Rule 33.3, Criminal Procedure Rules 2010 mandates contents of a full report, that is, one for submission in court, as follows:

- a. the findings on which they have relied in making the report or statement;
- b. details of which of the findings stated in the report or statement are within their own knowledge, which were obtained as a result of examinations, measurements, tests, etc. carried out by another person and whether or not those examinations, measurements, tests, etc. were carried out under the expert's supervision;
- c. the identity, qualifications, relevant experience, and any certification of the person who carried out the examination, measurement, test, etc.;
- d. details of any statements of fact, literature, or other information upon which they have relied, either to identify the examination or test requirements, or which are material to the opinions expressed in the report or statement or upon which those opinions are based;
- e. a summary of the conclusions and opinions reached and a rationale for these;
- f. a statement that if any of the information on which their conclusions or opinions are based changes then the conclusions or opinions will have to be reviewed;
- g. where there is a range of opinion on the matters dealt with in the report or statement, a summary of the range of opinion, and reasons for the expert's own opinion;
- h. any information that may cast doubt on their interpretation or opinion; and
- i. if the expert is not able to give an opinion without qualification, what the qualification is.

Much less specific is the legislated mandate for federal criminal prosecutions in the United States. Under Federal

Rule of Criminal Procedure 16, the Government must permit the defense to inspect and to copy or photograph the results or reports of any scientific test or experiment and must produce before trial a written summary of any proposed expert testimony that describes the witness's opinions, the bases and reasons for those opinions, and the witness's qualifications. Defense counsel in criminal cases has a reciprocal disclosure requirement. Despite the seeming generality of these terms, American courts have at times interpreted them to require some greater detail in the reports, such as underlying documentation.

In the United States, an additional requirement derived from the Constitution's guarantee of Due Process of Law may affect what must be included in a laboratory report issued by a police or other government agency. The prosecution must disclose information that is 'favorable to the accused' and 'material either to guilt or to punishment' as well as "evidence that the defense might have used to impeach the Government's witnesses by showing bias or interest." This extends to "evidence affecting credibility[.]" This information is generally denominated 'Brady material.'

The applicability of these rules to official [police or state] laboratories is settled. The US Supreme Court has held that the disclosure obligation extends to police agencies working with the prosecution, and this has been extended to forensic examiners. Hence, in a report or some other communication, a forensic examiner in government employ must ensure that 'Brady material' is disclosed.

What remains to be defined are the terms 'exculpatory' or 'impeachment' information. The core of each is easily described. Evidence is 'exculpatory' if it tends to reduce the degree of guilt or question proof of culpability; 'impeachment' information is proof of a bias or interest, or otherwise information that could be used to contradict or attack the credibility of the analyst or report. This type of disclosure parallels that of forensic laboratory reports imposed by the United Kingdom's evidence code. The code requires inclusion in the report of "a summary of the range of opinion and reasons for the expert's own opinion; [] any information that may cast doubt on their interpretation or opinion; and if the expert is not able to give an opinion without qualification, what the qualification is."

Reports: Stand-Alone Evidence or Support for a Testifying Expert

Whether a laboratory report may stand on its own as evidence in a trial, or instead must be accompanied by testimony of the forensic analyst, is a function of the law of the jurisdiction in which the case is tried. In the United States, a prosecution expert's report may not be admitted on its own, as this is deemed to violate the defendant's right to confront adverse witnesses. The Supreme Court in *Melendez-Diaz* versus Massachusetts held that a certificate of analysis fell within the core class of testimonial statements because it was a solemn "declaration or affirmation made for the purpose of establishing or proving some fact." In the 2011 follow-up of the *Melendez-Diaz* decision, the Court further held that another lab analyst may not come in to testify to the report's contents, at least where the other analyst neither supervised nor observed the initial

testing. [This applies only to prosecution expert reports, as in the United States only the defendant has a guarantee of the right to confront witnesses. Admissibility of a defense forensic report without examiner testimony would be determined by the state's rules of evidence, but is generally unheard of.]

At the same time, the confrontation right does not mean that the analyst must testify. A state may create a notice and demand statute under which the prosecution notifies the defendant of its intent to use an analyst's report as evidence at trial, after which the defendant has a specified period of time in which to demand the expert's live testimony. A defendant's failure to 'demand' waives the need for the analyst's presence and allows use of the report. As well, an accused may always agree to stipulate to the report's content, eliminating the need for any live testimony.

The Melendez-Diaz approach is not followed uniformly on an international basis. Canada permits proof by means of an expert report, without live testimony, where the proponent of the report has provided it to the opposing party and the trial court recognizes the author as a legitimate expert. The court retains discretion to mandate the expert's appearance for cross-examination. Australia's Evidence Act of 1995 similarly authorizes expert proof by certificate, but the opposing party may require the offering side to "call the person who signed the certificate to give evidence." In the United Kingdom, expert reports are themselves admissible as evidence, subject to the judge's discretion in requiring the analyst or examiner to appear.

Ethical Considerations and Forensic Reports

The decision of what to include in a forensic laboratory report, beyond that required by law or by science, may be informed by ethical considerations. Forensics organizations often have ethical codes, but they may be silent as to the particulars of report writing. Illustrative is the Code of the American Board of Criminalistics, which only asserts general obligations such as "[e]nsure that a full and complete disclosure of the findings is made to the submitting agency[.]" Other codes may not mention reporting at all but instead address only the delivery of information without distinguishing between the written report and a courtroom presentation of evidence. An exception is that of the Australian and New Zealand Forensic Science Society, Inc., which requires that a report be nonpartisan when results are ambiguous. "Where test results or conclusions are capable of being interpreted to the advantage of either side in a legal proceeding, each result or conclusion should be given weight according to its merit."

Ethical considerations may also be imposed by law. In the United Kingdom, the expert is deemed to hold only one allegiance, that to the court, regardless of the party who retained the individual. Specific ethical obligations are imposed for written reports. First, where there is a range of opinion, the expert must summarize the various positions. Second, if the opinion rendered cannot be given without qualification, the expert must disclose that and state the qualifying aspects or concerns.

Conclusion

Within and across nations, there is no clear standard for forensic reports intended for court use, except where prescribed by law. What should be manifest is that the more detailed the report, and thus the more it is capable of rigorous assessment by an independent expert evaluator, the more credibility will be attributed to both the results and the examiner.

Glossary

Facts in issue Facts contested at trial.

Trier of fact (also tribunal of fact or fact-finder) Responsible for factual determinations (i.e., guilt or liability) at trial.

Conventionally the jury, though in judge-only trials the judge is also responsible for fact-finding.

Voir dire A hearing to determine an admissibility issue before or during trial. The jury is usually absent to prevent them hearing, and being influenced by, evidence that may be deemed inadmissible and excluded.

Introduction

In legal institutions, the primary role of forensic science is to assist with proof. It provides evidence that assists the trier of fact (usually a jury) to determine guilt (criminal) – beyond reasonable doubt – or liability in civil proceedings – on the balance of probability. Mostly, this involves routine analytical and comparative processes that lead to reports that help with investigations and the production of guilty pleas. In a small proportion of criminal cases, accusations are contested, through trials, and on these occasions expert witnesses are often required to present their evidence (or testimony) orally in the form, usually, of incriminating opinions.

The stakes involved, especially in criminal proceedings, place a premium on the need for reliable forensic science evidence. Historically, judges have been inclined to allow forensic scientists and other investigators to testify, and sometimes speculate, regardless of underlying research. The past two decades have seen increasing interest in formal admissibility rules across civil justice and criminal justice systems, though the application of such rules to forensic science has been inconsistent, with courts preferring to rely on trial processes to expose questionable evidence.

Chain of Custody: Collection, Transport, Handling, and Storage of Samples

Most jurisdictions have legislation, or guidelines, regulating the collection and handling of samples that might be used for forensic purposes. Where the samples are taken from persons or their property, these tend to be conditioned by privacy concerns linked to constitutions and bills of rights.

Many of the problems associated with the collection, transportation, and handling of samples and materials have been substantially reduced, if not eliminated, through administrative solutions including enhanced labeling, tamper-proof bags, bar codes, and restricted access. While chain of custody, the continuity of exhibits and contamination all continue to raise problems, in recent years the primary epistemic challenges to forensic science evidence have focused upon validity and reliability, interpretations and expression of evidence, and the weight to assign expert opinions.

Admissibility of Forensic Science

To be admissible in criminal (and most civil) proceedings, forensic science evidence must be relevant and satisfy jurisdictional requirements for exception to the general rule prohibiting opinion evidence. In most jurisdictions, the party adducing the evidence, especially the state, must give notice of the expert evidence to opposing parties in order for them to take the evidence into account and provide an opportunity to take advice or obtain an alternative expert opinion. Failure to comply with formal rules, such as improperly obtaining samples or conducting an illegal search, for example, may lead to exclusion or require formal approval by a trial judge before any resulting evidence is admissible.

Challenges to forensic science evidence are usually focused on admissibility and weight. Admissibility governs what expert evidence can be presented to the trier of fact during the trial. The trier of fact can base their decision only upon admissible evidence. The weight of the evidence is the value of the evidence assigned by the trier of fact. It is shaped by the assumptions and prejudices they bring to the trial as well as the way opinions fare in response to direct and redirect (examination and reexamination), cross-examination, rebuttal opinions, and other evidence, opening and closing addresses, and any directions or warnings from the trial judge.

Admissibility Standards

Most forensic science evidence is classified as opinion evidence (as opposed to fact). Opinions are ordinarily inadmissible, though all jurisdictions maintain formal exceptions for the opinions of experts, such as forensic scientists. Historically, scientists and other expert witnesses were also prevented from expressing views directly on the issue to be determined by the trier of fact (e.g., murder, insanity, or negligence). Largely in abeyance, this (ultimate issue) rule was intended to prevent the expert from usurping the prerogative of the trier of fact.

Formal qualifications or experience, the existence of a 'field of knowledge' and evidence of 'acceptance' among relevant experts once grounded the admissibility of expert opinions. These standards prevail in the United Kingdom, New Zealand, and some United States and Australian states,

although there is a gradual trend toward the formal adoption of admissibility standards incorporating concern with the reliability of expert techniques and derivative opinions. This trend, most conspicuous in the United States and Canada, is often traced to an influential civil decision by the United States Supreme Court.

Daubert v. Merrell Dow Pharmaceuticals, Inc. (1993) explained that for admission scientific opinion evidence should be not only relevant but also reliable. *Daubert* included several criteria that might assist trial judges with admissibility determinations. In *Kumho Tire Co v. Carmichael* (1999) the Supreme Court effectively extended the application of these criteria to nonscientific forms of expert opinion evidence, though both cases reinforce the need for flexible gatekeeping. Interestingly, the International Association of Arson Investigators filed a brief in *Kumho* arguing that arson investigators were not ‘scientific experts’ and should not be subject to the *Daubert* standard.

In jurisdictions beyond the United States, there is often considerable interest in the availability and admissibility of facts (or data) underlying expert opinion evidence. These technical legal concerns, about the basis of opinions, may influence admissibility determinations, but increasingly are associated with the probative value (or weight) to assign to the evidence. Basis rules are intended to enable opposing parties to test the foundations of an opinion and put the trier of fact in a position to evaluate the process and any conclusion.

Admissibility decisions are often made after a *voir dire* (or *Daubert* hearing). They usually take place in court in the absence of the jury, though they are sometimes resolved through written submissions. Because the purpose of admissibility hearings is to screen out ‘charlatan’ experts who may dupe naive lay jurors, where trial judges sit without juries (i.e., summarily), admissibility standards and discretions tend to be relaxed. The law presumes that a judge can and will properly value (or weigh) evidence, and is capable of disregarding unreliable and prejudicial forms of incriminating expert opinion when determining liability or guilt.

In most jurisdictions, judges have a demonstrated tendency to admit incriminating opinion evidence and – based on submissions and objections – are more likely to scrutinize expert opinion evidence adduced by criminal defendants (and plaintiffs).

Mandatory and Discretionary Exclusions

In addition to formal admissibility standards, most jurisdictions confer powers, usually in the form of a discretion (e.g., United States Federal Rules of Evidence R403) to exclude otherwise admissible evidence – including expert opinion evidence. In some jurisdictions (e.g., many Australian states), this assumes the form of an obligation. Where otherwise admissible, if the probative value of expert evidence – that is, its ability to rationally influence the assessment of facts in issue – is outweighed by the risk of unfair prejudice to the accused or by the risk of misleading or confusing the jury, the judge may exclude the evidence. This discretion/obligation is intended to prevent weak and potentially unfairly prejudicial evidence from contaminating criminal proceedings by distracting the trier of fact, or wasting time and resources.

Admissibility Practice

The National Academy of Sciences (NAS) report, public inquiries, empirical and comparative studies cast doubt on both the effectiveness and distinctiveness of admissibility standards, including those associated with reliability. The various studies and reviews suggest that unreliable forensic science and forensic science of unknown reliability is routinely admitted in criminal proceedings.

In practice, courts in most jurisdictions prefer to admit forensic science testimony and leave questions about the value of the evidence to be contested in trial and determined by the trier of fact. Where the admissibility of evidence and concerns about unfair prejudice are raised, they are more likely to lead to caveats and qualifications to the expression of opinions than exclusion *per se*.

Courts in the adversarial tradition maintain considerable confidence in the ability of the trial and trial safeguards to identify, expose, and effectively convey problems with expert opinion evidence.

Expert Evidence at Trial

Once admitted, the probative value or weight of expert evidence may be contested during the trial.

Most expert evidence is presented orally, by a legally qualified expert witness, during the trial. Some jurisdictions have certification procedures that facilitate the admission of expert reports. Where, however, the evidence is contested, most jurisdictions require the analyst who performed the tests, or developed the conclusions, to testify in person. This requirement was recently emphatically restated in *Melendez-Diaz v. Massachusetts* (2009), where the United States Supreme Court rejected the contention that laboratory reports were admissible without the ability to cross-examine the forensic scientist. Ordinarily, the state leads incriminating oral evidence from the forensic scientist through a state-employed prosecutor. Then the defendant may, usually via counsel provided through public funds, cross-examine the witness. Thereafter, the prosecution may repair or clarify any issues raised during cross-examination through redirect (or reexamination).

The state usually presents its entire case before the defense makes some kind of insufficient evidence submission (e.g., no case to answer) or responds to the accusation with its own evidence. The defense has no formal obligation to prove anything, and any reasonable doubts pertaining to the defendant’s guilt should result in acquittal.

The defense may also call and examine witnesses, including expert witnesses, who may, in turn, be cross-examined by the prosecutor (and any co-defendants). Subject to resources and the availability of legally acceptable expert witnesses, the defense may adduce original expert evidence inconsistent with guilt or rebuttal evidence that challenges the incriminating forensic science called by the state.

Examination-in-Chief (or Direct)

The party calling the witness normally adduces evidence by questioning its witness with nonleading questions. The rule against leading questions is often relaxed for expert witnesses,

and in some jurisdictions (or where the judge is the trier of fact) the expert's report or conclusions might be substituted for examination-in-chief.

Cross-examination

The primary means for identifying and exposing limitations with expert evidence and (not unrelated) the credibility of expert witnesses is through cross-examination. During cross-examination, lawyers are entitled to ask leading questions and to explore issues relevant to the evidence and underlying techniques, as well as the abilities, experience, and qualifications of the expert witness, including prior opinions and performances, in detail.

Cross-examination may be confrontational and aggressive or the examiner might seek to calmly elicit information and concessions that raise doubt or positively support a defense raised by the accused.

Reexamination (or Redirect)

Following cross-examination, the party that called the witness may reexamine (i.e., redirect) to clarify or repair issues raised during cross-examination. Ordinarily, a party cannot cross-examine its own expert witness, though all other parties, including co-defendants, may cross-examine witnesses called by another defendant.

Rebuttal (and Defense) Experts

At trial, the accused may adduce expert evidence to provide an opinion or interpretation that is inconsistent with the case advanced by the prosecution (defense expert), or may call an expert witness to challenge the scientific evidence led by the state (a rebuttal expert). Rebuttal experts may retest samples and exhibits though usually, constrained by resources, their roles are restricted to criticisms of methods, interpretations, and conclusions. Since the state, in many instances, maintains a near monopoly on forensic science expertise, almost all of the expert witnesses called by defendants are retired forensic scientists, though some are academics.

One of the major problems for both the defense and the state is the availability and cost of experts (and testing). Necessarily, public funding for defense experts is much more constrained than expenditure on investigations and prosecutions. The state is far more likely to adduce forensic science evidence than the accused and the likelihood of expert challenge tends to be low, though particularly low in much of the United States. Tightening of resources and increasing privatization of forensic science services makes testing, including testing that may produce results consistent with nonguilt, more difficult to justify.

Expression of Opinions

The manner in which experts express their opinions has become a source of increasing controversy. In recent years, especially in the aftermath of the NAS report, the Goudge Inquiry, and the English Court of Appeal decision in *R v. T* (2010), it has become reasonably common for judges to regulate the

manner in which an expert may express his or her opinion in court. Such efforts are intended to facilitate admission while preventing expert opinions extending beyond what experimental evidence can support.

Rather than exclude forensic science evidence, lawyers and judges often facilitate an admissibility compromise by tempering (i.e., negotiating) the strength of the conclusion – almost always represented as conservative. That is, judges may require or approve weaker expressions (such as describing similarities rather than positively identifying a source) than those proffered by the proponent of the evidence.

Judicial Guidance to Jurors

In many jurisdictions, the judge is either required (e.g., most Australian jurisdictions) or retains a discretion (e.g., England and Wales) to caution the jury about types of evidence that are considered to be unreliable or problematic. The basis for these might be statutory or drawn from the collective experience of judges. Expert evidence, particularly forms of evidence used for comparison or identification (such as probabilistic DNA evidence), are usually included within the types of evidence that receive judicial comment. Judges often instruct juries about dangers with expert evidence and expert disagreement. Jurors are sometimes instructed that they might reject an expert's opinion, though jurisprudence is divided on whether juries can simply reject the uncontested opinion of a formally qualified expert.

Ultimately, decisions about the weight to attach to expert evidence are matters for the trier of fact. In practice, the jury is entitled to accept the opinion of a forensic scientist, even if the testimony is speculative and based on techniques that have not been thoroughly tested, or were obtained in circumstances that dramatically increased the possibility of error.

Appellate Review and Postconviction

Concerns about the conduct of the trial, such as the admission or exclusion of expert evidence, or the way in which an opinion was expressed, often manifest postconviction. Few, if any, jurisdictions allow interlocutory appeals on the admissibility of expert opinion evidence. Consequently, appellate courts normally consider appeals pertaining to expert opinion evidence in the context of a review of the entire case. Issues relating to the value of expert opinion may be considered alongside other incriminating evidence, such as admissions or other forensic science evidence, and in conjunction with knowledge about prior convictions and sentence. Furthermore, failure to object to forensic science evidence in preliminary hearings or at trial, even where there was no public funding for expert assistance, may limit the ability to raise the issue on appeal. Failure to take timely objection, whatever the explanation, is often treated as a bar to subsequent review.

Ordinarily, though especially where the case against an accused appears to be compelling, there needs to be some nontrivial oversight or problem for success on appeal. On review, an appellate court may uphold the conviction notwithstanding errors associated with the admission or, as is more likely, expression of expert opinions. In such circumstances,

the strength of the overall case is considered to be sufficient to sustain the conviction. In such circumstances, procedural errors or limitations may be characterized as harmless. Successful appeals usually lead to retrials – where mistakes identified on appeal should be addressed.

Separate from courts of appeal, several jurisdictions (such as England and Wales and Scotland) have established Criminal Cases Review Commissions – statutory bodies empowered to undertake independent reviews of questioned convictions. Such commissions are usually empowered to review convictions and refer questionable cases to appellate courts. Only appellate courts (and, in some jurisdictions politicians), however, can formally quash convictions (or order retrials). In addition, many jurisdictions have facilities for Royal Commissions, public inquiries and independent reviews following miscarriages of justice associated with serious or endemic problems with criminal justice practice (e.g., the Runciman Royal Commission, Goudge Inquiry, and various state forensic science commissions).

Legal Safeguards in Practice

Historically, admissibility standards, exclusionary discretions, the ability to cross-examine, adduce rebuttal expert evidence, and give warnings with the authority of the judicial office/bench were, along with appellate review (and prosecutorial restraint), conceived to provide a robust and fair response to the presentation, assessment, and review of incriminating expert opinions, the need for fairness and the risk of wrongful conviction. Recent empirical studies, however, have raised questions about the ability of the (adversarial) trial and appeal to adequately explore, convey and expose problems with forensic science and medicine evidence.

The frailty of trial safeguards, revelations about the problematic empirical foundations of many forensic sciences (see NAS), in conjunction with the synergistic effects of forensic science and nonscientific evidence, means that the rigorous enforcement of admissibility standards and the exclusion of insufficiently reliable expert opinion is probably more important than previously appreciated.

Lay Assessment of Forensic Science

Trials and appeals place decision-making responsibility – for admissibility, probative value (or weight) and the strength of the overall case – upon persons usually without scientific or technical training. This approach made sense historically because the vast majority of the evidence presented at trial was of a nontechnical kind – for example, witness testimony. The use of expert witnesses and reliance on forms of specialized knowledge has increased dramatically in recent decades. This not only affects the manner in which evidence is presented but may also impair the ability of lay participants to recognize limitations and regulate expert opinion at trial and on appeal.

The technical ability of jurors and judges remains the subject of ongoing controversy. Research, primarily from the United States, suggests that many judges do not perform much better than juries when assessing scientific and

technical evidence and that judges have difficulty understanding and applying reliability criteria, such as those associated with *Daubert*. Questions about lay legal participants (lawyers, judges, and jurors), particularly their ability to consistently and adequately understand scientific and technical evidence, remain unanswered.

Judges, for example, have not developed demanding admissibility standards or strictly enforced those admissibility standards indexed to the reliability of forensic science evidence. Rather, judges have tended to trust the state's investigative institutions, the trial and its safeguards.

CSI Effects

It has become increasingly common for lawyers, forensic scientists, academic commentators, and media outlets to claim that juries are susceptible to what is called the 'CSI effect.' The term derives from the popular American television program *CSI* (Crime Scene Investigation), which commenced broadcast in 2000, became the most popular television in the country for a time, spawned several spin-offs and imitators, and achieved global distribution and popularity. The program is usually structured so that forensic evidence definitively and unambiguously resolves the unknown facts about each case. It has been criticized for this tendency, as well as for exaggerating the capacity and resources available in forensic laboratories, for taking dramatic license with the job descriptions of forensic scientists (e.g., depicting them carrying weapons and making arrests), and for occasionally fabricating nonexistent forensic techniques. Because of these features, many have claimed that the television program has an effect, the 'CSI effect,' on the behavior of those participating in the criminal justice system. Some articulations of the 'CSI effect' merely claim that attorneys have adjusted trial tactics by, for example, explaining why the failure to recover a particular forensic trace from an individual does not necessarily prove that individual was not present. Others advance the more troubling claim that jurors are acquitting defendants in cases where forensic evidence is absent, cases in which they would have convicted had the television program *CSI* never existed. At present, the evidence that juror behavior has changed in this manner is weak. In addition, it is important to distinguish the 'CSI effect' from what has been called the 'Tech effect' – that is, more appropriate recalibrations of juror expectations in response to actual advances in forensic science and technology.

Plea Bargains and Interrogations

The vast majority of resolved criminal cases are settled through plea bargains. Forensic science evidence is a very regular feature of plea bargains with some types of forensic evidence (e.g., DNA and fingerprint 'matches') likely to lead defense lawyers to advise their clients to plead guilty. Indeed, it may reasonably be argued that the primary role of forensic evidence in some legal systems is to serve as a form of leverage in plea negotiations. Another role for forensic evidence is to serve a similar role in police interrogations. Persuading a suspect that forensic science implies his guilt is a common interrogation tactic. While reliable forensic science results provide a legitimate

basis for questioning, in the United States, for example, lying to a suspect about the existence or results of forensic testing does not render any consequential admission or plea inadmissible.

The failure to enforce reliability standards rigorously, in conjunction with the weakness of trial and appellate safeguards and the likelihood of conviction at trial, means that innocent individuals may sometimes plead guilty in order to avoid the risk of dramatically longer (or lethal) sentences if convicted after contesting an accusation at trial. To the extent that forensic sciences are not demonstrably reliable, they presumably contribute to some pragmatic compromises by innocent persons.

Duties of an Expert Witness and Expert Reports

Experts have always testified under oath or affirmation to tell the truth.

Largely in response to controversies (and parallel civil justice reforms), many jurisdictions have begun to impose a range of formal duties and obligations, sometimes codified (e.g., United Kingdom and Australia) on expert witnesses. These codes, particularly statutory codes and rules of court, tend to reinforce the duties of an expert witness: to act impartially (as a servant of the court rather than a party); to disclose conflicting opinions and bodies of thought; to readily concede limitations and critical literatures. English and Australian rules tend to require disclosure and transparency in expert reports and testimony. In addition, societies of forensic scientists and other professional organizations often maintain their own codes of conduct or ethical prescriptions for members.

There is, however, little evidence that the expansion of formal codes has led to improved expert performances, greater circumspection in testimony, or higher quality expert reports. With a few conspicuous exceptions (e.g., Michael West and Sir Roy Meadow), forensic scientists are infrequently prevented from testifying because of formal breaches and, even in the aftermath of scandal and judicial censure, forensic scientists are rarely disciplined by professional bodies.

Wrongful Convictions

Recent reviews of wrongful convictions in the United States, typically cases exposed by Innocence Projects where individuals were exonerated by DNA evidence, suggest that in a large proportion of these cases flawed or misleading forensic science testimony was admitted. These cases suggest that, for a variety of reasons, forensic science failed to correct investigators' beliefs in the guilt of innocent persons which had been formed on the basis of other forms of incriminating, though mistaken, evidence—such as eyewitness testimony and false confessions. Thus, forensic science has both contributed to and exposed wrongful convictions.

Wrongful convictions also reinforce how traditional legal safeguards and appellate review may struggle to identify and expose weaknesses in forensic science and other kinds of

evidence (e.g., eyewitness identification), or overcome their synergistic effects even when they are mistaken.

Expert Witness Immunity

Historically, forensic scientists have been immune from suit for negligence. However, recent developments in England and Wales, following *Jones v. Kaney* (2011), suggest that in some circumstances immunity may be lost, thereby potentially exposing expert witnesses to liability for mistakes caused through negligence, inadvertence, and incompetence.

Legal Systems: Adversarial and Inquisitorial

SC Thaman, Saint Louis University School of Law, St. Louis, MO, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Accusatorial (procedure) Procedure where criminal proceedings begin with a complaint by a party (such as the victim or a public prosecutor) and not as the result of an inquisitorial investigation by a judge.

Adversarial (procedure) Court procedure where evidence is produced by the parties (prosecution and defense) and the judge plays a neutral, passive role.

Confrontation (right to) Right of the defendant in a criminal case to be present when the witnesses of the prosecution testify and to question them.

Consensual (procedures) Court procedures where the parties agree to a resolution without requiring a full trial.

Customary law (procedures) Procedures that were used before inquisitorial and adversarial procedures developed, such as ordeals, duels, and use of oaths.

Dossier (investigative) File compiled by the investigative official during the preliminary investigation that contains all the evidence to be presented at trial.

Exclusionary rule Rule that prevents use of evidence, even if relevant and reliable, that was seized in violation of important constitutional rights of the defendant.

Inquisitorial (procedure) Court procedure, where the judge plays an active role in investigating the issues and

ascertaining the truth, and the parties play a more passive role.

Investigating magistrate Judge who carried out the preliminary investigation in early inquisitorial systems, and still does so in some countries, such as France and Spain.

Jury court (trial) Trial procedure where court is made up of one or more professional judges who decide issues of law and a group of lay judges, who, sitting alone, decide issues of fact and guilt.

Mixed court Court made up of one or more professional judges and a group of lay judges who deliberate together and together decide all issues of fact, law, guilt, and sentence.

Plea bargaining A type of consensual procedure in criminal cases where the defendant agrees to plead guilty to a charge and punishment that are arrived at through negotiations between prosecution and defense, and where no trial takes place.

Preliminary investigation Procedure of investigating a crime, determining the identity of the perpetrator(s), and the legal qualification of the criminal act, before the case goes to a trial court.

Presumption of innocence Doctrine whereby the court, which decides the issues of fact and guilt, should proceed from the hypothesis that the defendant is innocent, until the prosecution has proved guilt beyond a reasonable doubt.

Introduction

There has always been a multiplicity of penal court procedures. The differences in how criminal wrongdoings were unraveled and settled often depended on the mode of their commission, the relationship between victim and perpetrator, and the seriousness of the offense. Three models for the resolution of conflicts arising from criminal wrongdoings have their roots in ancient procedures, which have perhaps been common to all cultures. All were attempts to avoid the most primordial response to criminal wrongdoing: self-help and, in the case of homicide, blood revenge. All are relevant to the understanding of modern criminal procedure. These are (1) *consensual* semi-private resolution of the conflict through negotiations between victim or prosecutor and the accused; (2) *adversarial* resolution of the dispute in a public oral trial often before a panel of lay judges (jury); (3) and *inquisitorial* investigation and decision of criminal cases, conducted in its heyday by state officials obligated to ascertain the truth.

All these procedural modes are found in varying mixtures in most modern penal systems, albeit in different combinations, usually with one procedural mode dominating due to cultural and historical reasons. They, and the principles derivative therefrom, provide the substance for the great contemporary discussions about criminal procedure reform in

Asia, Latin America, the former Soviet Union, and other parts of the globe.

Criminal procedure consists of a sequence of acts or procedures conducted by officials aimed at determining whether crimes were committed, who committed them, and what their punishment, if any, should be. Criminal procedure reformers must assess the applicability of the three procedural modes to (1) the decision to arrest and commence a preliminary investigation; (2) the decision to detain the suspect pretrial; (3) the decision to charge a suspect with the commission of a crime; (4) the pretrial assessment of the sufficiency of evidence to allow the case to proceed to trial (preliminary hearing); (5) the decision as to guilt (the trial); and (6) decisions post-trial as to whether there was sufficient evidence to convict, whether errors were made that require a new trial or whether a person acquitted may be retried.

Some Historical Watersheds in Criminal Procedure Reform

Early modes of consensual and adversarial resolution of criminal disputes predominated in Europe up until the late middle ages and the Renaissance and still exist in communities in Africa, Asia, Latin America, and other parts of the world,

which still use customary law. In both systems, the victim (or his or her tribe) made an accusation and the suspect-defendant responded. Thus, early adversarial systems were usually always *accusatorial* in nature, that is, initiated by the victim as accuser. A variety of influences, both political and cultural, led to the development of a new system of criminal procedure on the European Continent. Politically, the rise of the nation state and absolute monarchy led to a politicization of criminal procedure with the state replacing the victim as initiator of criminal proceedings. The vertical hierarchy of such systems was reflected in a vertical hierarchy of courts and a huge royal judiciary to administer it.

Culturally, the law was heavily influenced by the Roman Catholic canon law's inquisitorial procedures and formal rules of evidence and by the rediscovery of Roman law in the Italian universities. Judges began to see themselves (or to be seen) as truthseekers who, armed with the newly articulated Roman legal principles emerging from the Italian universities and with the rules of formal proof emanating from the Canon law, could achieve a superior quality of justice than that achieved by the irrational forms of procedure used by the Germanic tribes: ordeals, oath-helpers, duels, and lay decision makers.

The judges were royal officials beholden to the monarch and with no fealty to the communities in which their judgments would resonate. Punishments were considerably more Draconian than in the early middle ages. Procedurally, the most radical innovation was that of a formal preliminary investigation initiated *ex officio* and conducted by a judicial official who would examine the suspect and the witnesses, conduct other investigative acts, and record all his findings in a written document. Because no accusation by the victim was required, the new procedure was called *inquisitorial*. The written results of this preliminary investigation were compiled in an investigative dossier, which became the exclusive record upon which the decision of guilt or innocence would be based. If, under the formal rules of evidence, enough indicia existed to constitute what we might today call probable cause or reasonable suspicion that the suspect was guilty, then the investigating magistrate could order the suspect to be tortured if he or she refused to be examined.

There was no oral, public trial before a jury, but a secret written review of the findings of the investigating magistrate contained in the written investigative dossier. There was no right to counsel. At no time did the defense confront the prosecutor or the victim in an adversarial setting as exists today.

Judges had no discretion to mitigate the harshness of the findings. Unlike the jury, which continued to function in England, the judges could not reject the result mandated by the rules of evidence and acquit against the strictures of the law. The lay judges, who dominated in the earlier procedures, were gradually eliminated in favor of a purely 'professional' and more administrative than litigious form of justice.

The oral tradition persevered, however, in England and to an extent in Scandinavia. Oral, public trials by a jury of 12 gradually replaced ordeals and duels by the Thirteenth Century. Verdicts had to be unanimous and the ensuing judgments were final, not allowing of any posttrial review. Other than a brief examining of witnesses and suspects for purposes

of determining release on bail, there was no preliminary investigation. Victims or their lawyers brought the case and the defendant defended usually without a lawyer until the eighteenth century.

With the advent of the French Revolution, these two systems confronted each other and led to a new mixed form of procedure on the European Continent. The French revolutionaries, inspired by Enlightenment criticism of the brutality of inquisitorial criminal procedure by such great thinkers as Beccaria, Montesquieu, and Voltaire, and influenced by the antiauthoritarian credentials of English jury trial provided by the notorious acquittals of William Penn and other dissidents against the instructions of royal judges, introduced the public, oral English jury system, eventually grafting it on to the secret, written, inquisitorial preliminary investigation.

The French Declaration of the Rights of Man in 1789 and the American Bill of Rights of 1791 constituted the first great human rights revolution, which impacted upon criminal procedure, leading to its gradual humanization by protecting the criminal suspect from the arbitrary and pitiless power of the state. The American Bill of Rights proclaimed the right to protection against cruel and unusual punishments and against unreasonable searches and seizures, protection against self-incrimination, and a host of trial rights, including the right to counsel, to subpoena witnesses for the defense, to cross-examine or confront the witnesses of the prosecution, and the right to a speedy, public trial by a jury of the defendant's peers. All these rights were meant to protect against overreaching by the state: either by violating important rights of defendants during the gathering of evidence, or in assuring that the defendant would not be tried on the basis of written evidence prepared by the state in secret, without input or checking by the defendant through cross-examination. The presumption of innocence was proclaimed by the French Declaration and was held to be implicit in the due process rights granted by the American Bill of Rights.

Although jury verdicts were final, as in England, French juries were asked to answer a list of specific questions related to the elements of the charged crime(s) and the guilt of the defendant(s) contained in a special verdict, which sometimes included dozens if not hundreds of questions. The inquisitorial, written tradition on the European Continent preferred *reasoned judgments* and a particularized special verdict would make the jury's reasoning process clear and better facilitate appellate review of their verdicts. Often the professional judges themselves would legally evaluate the substance of the jury's factual questions and themselves pronounce judgment, thus limiting the autonomy of the jury's finding of guilt. The French jury model, in which a jury of 12 was presided over by three professional judges and in which only a majority verdict was required, was adopted by nearly all European countries in the nineteenth century. In Germany, a mixed court, composed of one professional judge and two assessors, in which lay and professional judges collegially decided questions of fact, law, guilt, and sentence, developed in the mid-nineteenth century for the trial of lesser offenses.

The continental European mixed system and the Anglo-American system of adversarial jury trial were spread through colonization, imperialism, and systematic borrowings into Asia, Africa, and Latin America. Ironically, many of the Latin

American countries, which liberated themselves from Spanish and (in the case of Brazil) Portuguese rule in the early nineteenth century, remained with the purely written inquisitorial procedures conducted exclusively by professional judges that had existed before the French Revolution and rejected the reforms that swept the European continent. Only Brazil, Panama, Nicaragua, and El Salvador introduced trial by jury but largely limited the jury to reading the contents of the inquisitorially prepared investigative dossier.

Jury courts were always controversial on the European continent and many jurists sought to abolish them or convert them into mixed courts. This was finally accomplished by the totalitarian regimes of the first-half of the twentieth century and juries vanished in many countries to be replaced by mixed courts or purely professional panels: in 1917 in Russia, 1931 in Italy, 1939 in Spain, and 1941 in Vichy, France. Jury trials, introduced in 1928 in Japan, were suspended in 1943. Jury trial was eliminated in Germany in favor of the mixed court before the rise of Nazism to power, but by decree in 1924.

After the defeat of Nazism and Fascism in World War II, Italy, France, and Germany did not return to the classic jury, preferring the *mixed court*. The mixed court cemented the dominance of the professional bench over its lay component by enabling the judge to personally influence the lay judges in how they decided the question of guilt. It also was more consistent with the necessity of giving reasoned judgments in all criminal cases.

The horrors of World War II and the holocaust, and the crimes of the totalitarian regimes led to a new era of human rights with the adoption of the Universal Declaration of Human Rights, International Covenant for Civil and Political Rights, and the European, American, and African Conventions on Human Rights. The European Court of Human Rights has had great influence in the reform of European criminal procedure in interpreting the European Convention. In the wake of this revolution and with the democratization of Germany, Italy, France, and Japan after 1945 and Spain after Franco's death, these countries began to systematically eliminate many of the negative vestiges of the old inquisitorial systems, which had survived in mixed form since the French Revolution.

A distinct return to adversary and consensual procedures has been noticeable since the late 1980s. The 1988 Italian Code of Criminal Procedure introduced an adversarial trial system and several forms of consensual resolution of the guilt issue, without returning to trial by jury. Russia, on the other hand, reintroduced adversary procedure and the jury in 1993 and a form of consensual resolution of cases in 2001. The majority of the former Soviet Republics have followed the Russian model, though only Georgia, so far has introduced trial by jury. Spain strengthened the adversarial nature of its trial system by introducing trial by jury in 1995.

The Adversarialization of the Inquisitorial Preliminary Investigation

The centerpiece of inquisitorial procedure was always the preliminary investigation, traditionally carried on by an investigating magistrate who was usually a member of the judiciary. Even after the inquisitorial systems reformed to include an oral

trial by jury, most systems allowed reading of the reports, including those of forensic experts, contained in the investigative dossier before the trial court. This constituted a pre-packaging of evidence with no opportunity for the defense to see or confront the witnesses. Some countries allowed a minimal amount of participation of counsel. For instance, after 1897 France allowed participation of counsel during judicial interrogations of the suspect, but this was of little help to the suspect because his or her interrogation by the police was always in secret with no right to counsel.

Substantial changes in the inquisitorial preliminary investigation only occurred after the second human rights revolution following World War II. The role of a judicial official as investigator began to be questioned: how can a judge who is following his or her particular theory of guilt in a case be independent, neutral, and judicial when issuing arrest, search, or wiretapping warrants? Because it was the police who, in reality, conducted the lion's share of the actual criminal investigation, and because it was the prosecutor who was responsible in most countries for preferring the charges, it was decided to put the prosecutor in charge of the preliminary investigation and reduce the judicial role to that of a liberty or control judge, a neutral arbiter of invasions of human rights (authorizations of arrests, seizures, searches, and wiretaps) who would also preside over interrogations. This step was taken in Germany in 1974, in Italy in 1988, and in Venezuela and other Latin American countries in the 1990s. The prosecutor, however, continued to maintain the inquisitorial control of the investigation and determined which witnesses and experts would testify in the case. In Spain, new legislation, such as the 1995 jury law, has transformed the investigating magistrate into a more neutral pretrial judge by allowing him or her to investigate only in response to a request by either the public or private prosecutor (victim) or the defense.

In the Soviet Union and formerly socialist Eastern Europe, it was the public prosecutor who not only generally directed the preliminary investigation, which was in the hands of an investigator provided by the Ministry of the Interior, but also authorized all invasions of protected human rights of suspects. The former socialist countries, which have since ratified the European Convention of Human Rights, have gradually introduced new legislation requiring judges to perform these important functions and the ex-Soviet republics of Central Asia are gradually following suit.

Protection of suspects from secret, custodial counsel-less interrogations was greatly influenced worldwide by the famous decision of the United States Supreme Court in *Miranda v. Arizona*, 384 US 436 (1966). Today, most of the formerly inquisitorial systems of continental Europe, the former Soviet Union, and Latin America, as well as South Korea require law enforcement officials to advise suspects of their right to remain silent and their right to counsel before being questioned and many new codes of criminal procedure, such as those of Italy (1988) and Venezuela (1998), require counsel to be present during all interrogations.

Increased recognition of the right to confront witnesses, guaranteed by Art. 6(3)d of the European Convention of Human Rights, has led formerly inquisitorial countries to require presence of the defendant and or defense counsel during the examination of prosecution witnesses during the

preliminary investigation, where possible. The European Court of Human Rights has repeatedly condemned the use of written statements where they are the sole or main evidence of guilt in criminal cases if the defendant had no chance pretrial to confront and examine the witness. The 1988 Italian code requires the prosecutor to initiate a hearing to preserve witness testimony in cases where there is fear that the witness may not be available for trial at which defendant and victim have the right to be present and examine the witness, or else the statement cannot be admitted at trial. Similar provisions exist in the 1995 Spanish Jury Law and in new Latin American codes of criminal procedure. Thus procedure in formerly inquisitorial countries is approximating that in the United States, where the inadmissibility of written statements has been strengthened even further following the decision of the US Supreme Court in *Crawford v. Washington*, 541 US 36 (2004).

In Italy and in cases subject to Spain's new jury law, the preliminary investigation is supposed to be the stage for only determining whether sufficient probable cause exists to charge the suspect, and not for preparing evidence to be used at the trial. Any evidence that could be presented at trial and is not required for a showing of probable cause need not be taken during the preliminary investigation. In this sense, the preliminary investigation tends to resemble the American grand jury or preliminary hearing. In fact, the investigative dossier is, in principle, not to be used during the trial as a source of evidence. A special trial dossier is compiled, including the accusatory pleading and any evidence that has been properly preserved for trial, guaranteeing defense rights of confrontation as noted above.

Some formerly inquisitorial countries have gone a step further, however, by allowing parallel defense investigations as exist in the United States. The 1988 Italian Code provides for defense gathering of evidence in preparation for the trial phase and amendments in 1999 provide for detailed procedures to regulate the gathering of this evidence and its eventual unification with the prosecution evidence in a common investigative file. The Russian code of 2001 has also taken the step to allow defense investigations.

The Decline of the Inquisitorial Trial Judge

The trial judge in the nineteenth century mixed systems on the European continent acted like the quintessential investigator. After reviewing the investigative dossier, he decided which witnesses would be called, and himself did the examination of the witnesses at trial. As he had reviewed the investigative dossier and had it at hand, he was aware of the inculpatory premises put forward by the investigating magistrate and had usually adopted them, for he had to decide pretrial whether there was sufficient evidence to set the case for trial. It stretches the imagination to believe that such a trial judge actually entertained a presumption of the innocence of the defendant in such a procedure. Not unsurprisingly, the written judgment would often closely follow the language of the written accusatory pleading.

On top of that, the defendant was called to answer the charges at the beginning of the trial in front of the jury and asked to give a statement before any other witnesses were called

or evidence presented, seemingly belying the fact that the burden was on the state to prove the charges. The judge then examined the defendant, using the materials in the dossier to guide him or her in the 'search for the truth.' The prosecutor and defense counsel would be able to submit questions (often only in writing to the presiding judge) to supplement the examination of the judge. If witnesses did not appear, the presiding judge would merely read the statements they had made to the investigating magistrate during the preliminary investigation.

As long as European systems still had juries, the trial judge was not a judge of the facts and, therefore, the fact that the judge was not neutral did not necessarily directly affect the outcome of the case. But when most European systems, and Japan, eliminated the jury in favor of professional or mixed panels, then the same judge who 'investigated' the case at trial using his/her inquisitorial skills and who had adopted the findings of the investigating magistrate, also decided the case, which appears to violate the presumption of innocence.

This system, which still largely exists in France, Germany, the Netherlands, Belgium, and other countries, is gradually being replaced by the adversarial model where prosecution and defense are responsible for preparing and presenting the evidence and witnesses, including expert witnesses, and questioning them, and the judge assumes a more passive role: deciding questions of admissibility of evidence and making sure the parties have 'equality of arms' in presenting their cases.

The Italian code of 1988 was the first to take the radical step of eliminating the preliminary investigation dossier from the courtroom. Spain followed suit in its 1995 jury law, as did Venezuela in 1998. Italy also eliminated the presiding judge's duty to determine the truth, which was important, because, unlike in Spain and Russia, Italy did not return to the jury, and the judge thus still remains a trier of fact. In 1992, the Russian Constitution had already been amended to provide for adversarial procedure and trial by jury. Jury trials began in 1993 in a handful of provinces, but since the 2001 code of criminal procedure, they exist throughout the country. Most of the former Soviet Republics have also turned to adversary procedure, with only Georgia having introduced the jury in 2010.

Since 1990, most Spanish-speaking Latin American countries have moved away from the old pre-Napoleonic inquisitorial systems to an accusatorial-adversarial system. Latin America, however, has by and large remained with professional judges although the Argentinian province of Cordoba, Venezuela, and Bolivia have introduced mixed courts. El Salvador and Nicaragua have modernized their old inquisitorial jury systems within new adversarial codes of criminal procedure and the jury is being discussed in Argentina. Japan and South Korea also introduced new mixed court systems in 2009. The Soviet mixed court, which replaced the Russian jury court in 1917, was adopted in nearly all countries in the socialist bloc following World War II and most of these countries, whether or not they have become democracies, continue to use a court composed of one professional judge and two lay assessors in criminal cases (Poland, Czech Republic, Hungary, China, and Vietnam, among others).

The 'search for truth' at all costs during the criminal trial has also suffered as a result of a growing recognition that evidence gathered in violation of the human rights of criminal suspects

(usually violations of the right of privacy, the right to human dignity, or the privilege against self-incrimination) should not be used in the criminal trial even if it is otherwise relevant and credible evidence of guilt. The United States took this step in 1961 with the landmark decision of *Mapp v. Ohio*, 367 US 643 (1961), which recognized an exclusionary rule in relation to illegally gathered evidence. In most Western countries, however, the search for truth still prevails in the end because the courts take a very cautious approach to exclusion of evidence, engaging in an elaborate balancing process, which in the end only excludes evidence gathered in the most egregious ways (Germany, England and Wales, Canada, Australia, and New Zealand). In Italy and Spain, the legislatures have passed laws that require exclusion of such evidence, yet only the Spanish courts have enforced this law with any vigor. The Russian Constitution of 1993 mandates exclusion of illegally gathered evidence as do most of the new post-Soviet constitutions and many new Latin American constitutions.

The Eclipse of Adversarial and Inquisitorial Procedure?

Although adversarial principles have been triumphing over their inquisitorial counterparts in modern criminal procedure reforms, the reality is that criminal procedure today is increasingly inclined toward avoidance of the full trial through plea bargaining or other consensual procedures, as a result of which no trial is actually held. In the United States, over 95% of all cases are decided by guilty pleas, which are often prompted by the threat of Draconian sentences if the defendant goes to trial and loses. Since the Italian code of criminal procedure of 1988, which introduced several types of consensual avoidance of a full trial, similar to plea bargaining, nearly all European countries have followed suit, and guilty pleas or stipulations are rapidly replacing trial as the mode of resolving criminal cases.

Although the agreement between the parties smacks of adversarial procedure, the pressure placed on the defendant to admit guilt reminds one of the old inquisitorial practices of inducing confessions.

Glossary

Adversarial model An adversarial system is a legal system where the role of the court is primarily that of an impartial referee between the prosecution and the defense.

Circumstantial evidence Circumstantial evidence is evidence in which an inference is required to connect it to a conclusion of fact. It allows a fact finder to deduce a fact exists.

CSI It is an American television crime drama. CSI is short for Crime Scene Investigation, and the show follows a team of investigators who solve grizzly crimes by subjecting the physical evidence to various forensic techniques in a high tech lab.

Falsifiability Falsifiability of an assertion, hypothesis, or theory is the logical possibility that it can be contradicted by an observation or the outcome of a physical experiment.

Forensic odontology It is the application of the science of dentistry to the field of law. It includes the identification of unknown remains, bite mark comparison, the interpretation of oral injury, and dental malpractice.

Forensic science It is the use of science to answer legal questions.

Inquisitorial model An inquisitorial system is a legal system where the court or a part of the court is actively involved in investigating the facts of the case.

Introduction

After watching a few nights of television, viewers may believe that all criminal cases are solved with science. Popular television shows such as *CSI* provide a story line that assumes that the criminal justice system seamlessly weaves science into police practices and courtroom evidence. The reality is not so simple, but it is a lot more interesting. Law is a consumer of science. It uses science to answer important questions – just like characters on famous television shows who ask ‘Who shot the fatal bullet?’ or ‘Was the deadly fire intentionally set?’ But law has continually wrestled with what constitutes science for legal purposes, who counts as an expert in the courtroom, and how much weight the court should give expert scientific testimony.

In 2005, at the behest of the forensic science community, the US Congress commissioned the National Academy of Sciences (NAS) – one of the world’s premier sources of independent, expert advice on scientific issues – to report on the past, present, and future use of forensic science in the United States. The academy spent 2 years collaborating with legal and scientific scholars and practitioners. It heard over 80 witnesses during 16 days of testimony. Then in 2009, it issued a landmark report solidifying its findings.

The report questioned the methodology of some disciplines and criticized the lack of mandatory, standardized testing procedures in others. It condemned some disciplines for interpreting test results to support conclusions of ‘individualization,’ that is, claims that an absolute ‘match’ can be made between a crime scene specimen and an individual source, such as a suspect. The report concluded that ‘With the exception of DNA analysis . . . no forensic method has been rigorously shown to have the capacity to consistently, and with a high degree of certainty, demonstrate a connection between evidence and a specific individual or source.’ It also expressed extreme doubt in the existing legal framework to adequately address the limitations of the forensic science disciplines. Soon after, the US Supreme Court noted that

forensic sciences are subject to ‘serious deficiencies’ that may have contributed to wrongful convictions.

Over the years, many forensic communities have implemented safeguards and developed new scientific theories that improve the reliability of their discipline, some of which were noted by the 2009 NAS report. Most courts, however, are still failing to discern the differences between valid and invalid science and are reluctant to corral exaggerated testimony by certain experts in these fields. The courts’ failures are understandable. In their quest for discovering the truth, science and law take different paths. Law serves as a way of organizing and stabilizing societies, whereas science seeks to know and understand the natural world. Because law and science use different processes, when science changes, as it inevitably does, law responds slowly, reluctantly, and often inconsistently.

The Filtering of Scientific Evidence into Courtrooms

In courtrooms, advocates use scientific evidence to bolster their arguments and sway the decision maker. Judges commonly act as referees in a tug-of-war between advocates claiming that their science answers the relevant legal questions better than their opponent’s. Judges act as gatekeepers filtering all types of evidence that comes into the courtroom, including scientific evidence. They decide whether the evidence is relevant, helpful to the fact finder, and sufficiently reliable. As science has advanced, the methods courts use to filter scientific evidence have gradually changed as well. The current legal regime for the admission of evidence in the United States was pronounced in *Daubert v. Merrell Dow Pharmaceuticals*. *Daubert* demands judges assess the proffered scientific opinion themselves by asking whether the expert’s ‘underlying reasoning or methodology is scientifically valid and can properly be applied to the facts at issue.’ The *Daubert* court provided these guidelines for courts to assess experts’ opinion evidence: (1) whether the subject matter can be and has been tested,

(2) whether the known error rate associated with the use of the science is too great, (3) the quality of the methodology or the degree to which the methodology has been subjected to peer review, and (4) the methodology's general acceptance in the scientific community.

Daubert forced judges to become informed consumers of scientific evidence. Judges must make sophisticated decisions about whether an expert's methodology is scientifically valid and reliable. A number of courts in jurisdictions outside the United States have found *Daubert* helpful in assessing the reliability of expert evidence. But critics claim that judges are not scientists and are not equipped to determine what methods are scientifically valid. Thus far, this criticism seems warranted.

Law as an Adversarial System

Several countries rely on the adversarial model to arrive at truth. This system assumes that when two adversaries present their best evidence and make their best arguments, the judge or jury will choose the more persuasive argument. However, recognizing that the strongest arguments may not always be true, the law erects procedures designed to protect against a slightly better argument that happens to be wrong. For instance, in a criminal case, the law requires that a jury find the defendant guilty beyond a reasonable doubt. Science, on the other hand, understands that our experience and reason often lead us astray. Science would never assume that the most persuasive answer is the correct one, even if it seems true beyond doubt. Instead, it proposes ideas that can be tested rigorously and empirically. It relies on a community of scientists who scrutinize and continue to test even the most persuasive hypotheses.

The adversarial system includes flaws that often allow questionable science into the courtroom. The ideal adversarial system assumes equal parties with equal resources and equal access to the evidence. In reality, this equality does not exist in the criminal justice system. First, many forensic scientists are an insulated part of the law enforcement team. They work hand in hand with law enforcement officers to solve crimes. Their methods are often shrouded in secrecy because law enforcement officers have access to evidence, testing, and reports, but the defendant does not enjoy the same rights. Defendants often lack access to laboratory notes, independent testing, and the performance reports of the scientists whose conclusions they wish to challenge.

Defendants also suffer from a lack of resources. Courts often deny defendants access to scientific experts, and even when defendants are given the resources to hire independent experts, few independent crime laboratories exist. When defendants present scientific expert testimony to challenge the state's case, those experts are regularly attacked as biased because they have been paid by the defendant to give testimony in the case. The prosecution's witnesses, on the other hand, do not face the same perceived biases because they often work for law enforcement, and they are not paid for their testimony in any one particular case. Although veterans in the criminal justice system understand that independent experts must charge fees for their work, attacks on hired experts' credibility can diminish their testimony with unsophisticated jurors, a bias that generally hurts defendants more than prosecutors.

In countries that employ an inquisitorial justice system rather than an adversarial model, the judge plays a more active role in truth seeking. The judge may choose the experts, question the witnesses, and step in when attorneys fail to adequately represent their clients. This is the case in many European countries, where judges are part of the civil service. This system, like some adversarial systems, relies on judges to sort and weigh scientific evidence, and sometimes they get it wrong. This is not surprising given that judges are not scientists and therefore are often unequipped to discern reliable from unreliable scientific testimony. A high profile example of this took place in France, which operates under the inquisitorial system. In the French town of Outrea, 13 individuals were convicted of child molestation based, in part, on the testimony of psychiatrists. When years later the key witness admitted that she had invented the whole story, the French government held a special parliamentary inquiry to investigate the case, which it labeled a '*catastrophe judiciaire*.' The inquiry focused attention on the errors of the magistrate judge, noting that the judge had allowed the hasty, biased, and ultimately unfounded conclusions of psychiatric experts to taint the process. The 13 defendants were eventually exonerated after spending years in prison.

Law's Reliance on Past Decisions

Law aims to provide stability and predictability. People need to know how the law will be applied to make important decisions about their lives; therefore, the law relies on past decisions to give it predictability. Although this method does not always ensure that courts make accurate decisions – they could simply be repeating the same mistakes – it does provide the public with predictability. Conversely, when science seeks an answer, it assumes that everything that has come before could be incorrect. Science assumes that the ideas we accept today will be modified or rejected in favor of new ideas supported by further evidence.

Arguably, the law's need for predictability has driven the courts' treatment of fingerprint evidence. For over a century, the practice of 'matching' a crime scene print to an inked suspect print, known as friction ridge analysis, has gained universal acceptance. In 2004, the case of the American lawyer, Brandon Mayfield, undermined the alleged infallibility of this practice when some of the most prominent examiners in the FBI erroneously linked Mayfield's print to a print associated with the Madrid Bombings.

However, even before the Mayfield case, the admissibility of fingerprint evidence had been challenged in the American courts. These challenges were largely unsuccessful; only a few appellate courts found that trial courts were wrong to simply accept that 'human friction ridges were unique and permanent.' In *U.S. v Crisp*, the issue of fingerprints splintered the Fourth Circuit Court of Appeals. In a dissent, one judge argued that 'the history of fingerprint identification and the dogged certainty of its examiners are insufficient to show that the technique is reliable.' In 2007, a Maryland court refused to allow an examiner to testify that a crime scene print 'matched' the defendant's print because the discipline was 'a subjective, untested, unverifiable identification procedure that purports to

be infallible.’ In 2009, the NAS report warned that there was ‘limited information about the accuracy and reliability’ of fingerprint analysis and that examiners should better document their work. In a few post-NAS decisions, courts have acknowledged the report’s concerns about overstated ‘matches,’ the need for more uniformity and research, and that the long-term use of fingerprints cannot itself justify admissibility. Still, these courts, and nearly all others, continue to admit fingerprint evidence without hesitation, luxuriate in the discipline’s alleged low error rate, and reject the notion that examiners cannot make a certain ‘match.’

Until recently, fingerprint evidence was rarely challenged in trials or appeals in England and Wales. However, in 2011, opinions began to shift. In *R v Smith*, conflicting evidence given to the Court of Appeal (COA) by multiple fingerprint experts caused the COA to quash the appellant’s murder conviction. The COA called for fingerprint evidence to be more widely investigated and cited the ongoing Scottish Fingerprint Inquiry. This inquiry was triggered after a former Scottish police officer, Shirley McKie, was prosecuted for perjury. McKie had testified at a murder trial that she had not entered the crime scene, but a print at the scene allegedly ‘matched’ her fingerprint. McKie was later acquitted when evidence demonstrated that the alleged ‘match’ was false.

In 2010, the International Association for Identification (IAI) – the world’s oldest and largest forensic science and identification association – officially changed its position in relation to friction ridge examinations because of scientific advances. The IAI now accepts that friction ridge skin impressions can share varying levels of commonality with multiple sources and emphasizes that print examiners should offer clear conclusions based on mathematical models, that is, statistics of probability. In other words, examiners are encouraged not to testify in terms of matches ‘to the exclusion of all others.’ Despite these shifts in standards, courts have failed to develop a consistent approach to fingerprint expert testimony, and testimony permitted in one case may be ruled wholly unacceptable in another case.

Law as an Arbiter of Disputes

Although both law and science aim to discover the truth, law is concerned with resolving disputes. Law prefers a resolution that is timely and permanent. For example, when litigants claim that ingesting a prescription drug caused serious health problems, the law cannot wait for years of rigorous testing. Instead, it relies on the most persuasive arguments at the time. If those arguments turn out to be inaccurate, the law does not readily revisit the earlier decision. The case is final. Science, on the other hand, is comfortable with a slower process of discovery. It assumes that proper testing may take years or even decades before reliable determinations can be made. It also assumes that long-held principles are subject to falsifiability and that when enough evidence mounts against a particular hypothesis, the hypothesis must give way.

Courts often cite the need for finality in criminal convictions secured on the basis of outdated, unreliable science. For example, in 2004, Cameron Todd Willingham was executed in Texas based on outdated arson assumptions. The state

theorized that Willingham set fire to his family home, killing his three young children by using an accelerant. At trial, arson investigators testified that the fire displayed around 20 hallmark signs of arson, including pour patterns, spiderweb glass, brown stains on the floor, and V-shaped soot marks. Like most investigators, they had picked up these hallmarks after years of experience in the field.

Shortly before Willingham’s execution, Dr. Gerald Hurst, a globally acclaimed scientist and fire investigator, produced a report for the Governor of Texas and the Texas Board of Pardons and Paroles (who were both Willingham’s last hope for relief) that critically undermined the basis of the state’s case. The report harkened back to an elaborate experiment in 1990, the Lime Street Fire Experiment. Without using an accelerant, investigators set fire to a couch in a house and watched as flashover, the point at which radiant heat causes a fire in a room to become a room on fire, occurred. In short, investigators found that what they thought were classic signs of arson, such as pour patterns and V patterns, can also appear on their own, without an accelerant, after flashover. Hurst reported these advances and explained that brown stains are common in fires as a result of charred debris mixing with water from fire hoses. In addition, he reported that spiderweb glass is produced by rapid cooling when fire hose water hits hot glass. Hurst’s report was ignored. As it turned out, the Texas courts and the Governor opted for the finality of Willingham’s execution when there was no reliable scientific evidence that a crime had even occurred. Numerous courts have followed suit and have rejected claims for relief, even though advances in fire science completely undermine the untested techniques that were used by investigators decades ago.

The Law Requires Binary Decisions

The law forces decision makers into binary decisions: Guilty or not guilty? Causation or no causation? Match or no match? Science, on the other hand, allows for more ambiguous or nuanced positions that are expected to evolve. When forced into binary decisions, it is no surprise that judges often fail to limit the scope of scientific evidence, allowing testimony that offers certainty where absolute certainty cannot exist.

Firearms identification evidence is a good example of the courts having allowed examiners to testify in bold absolutes when there is no scientific foundation for such conclusions. Firearms evidence has been used for over 80 years without much reliability testing. When the hard metal of an internal part of a gun connects with the softer metal of the ammunition, it makes a ‘toolmark’ on the ammunition. Toolmark examiners routinely testify that tools make reproducible, unique characteristics that allow them to determine that a specific gun fired a particular bullet to the exclusion of all others.

This sort of testimony came under fire in the new millennium, and since 2005, many courts have set about diluting the conclusions of examiners. Courts from California to Massachusetts have prohibited examiners from testifying to ‘matches’ in terms such as ‘to the exclusion of all others in the world’ and have instead insisted on phrases such as ‘a reasonable degree of ballistic certainty’ and ‘more likely than not.’ In *U.S. v. Green*, Judge Gertner reluctantly admitted firearms evidence,

because of my confidence that any other decision will be rejected by appellate courts, in light of precedents across the country. . . . While I recognize that the *Daubert* standard does not require the illusory perfection of a television show (*CSI*, this wasn't), when liberty hangs in the balance – and, in the case of the defendants facing the death penalty, life itself – the standards should be higher than . . . have been imposed across the country. The more courts admit this type of toolmark evidence without requiring documentation, proficiency testing, or evidence of reliability, the more sloppy practices will endure; we should require more.

Judge Gertner's opinion suggests that there is a fear among the judiciary of upsetting the current predictability of the criminal justice system. It appears that judges are keen to preserve the status quo despite new developments in scientific understanding.

Judge Gertner's concerns were echoed in two subsequent reports. In 2008, a NAS report found that the 'validity of the fundamental assumptions of uniqueness and reproducibility of firearms-related toolmarks has not yet been fully demonstrated.' Likewise, the 2009 NAS report found that too little was known about the variables among individual tools and guns and that insufficient studies existed to understand the reliability and repeatability of firearms analysis. The report also criticized the lack of precisely defined processes for examiners to follow in their analysis and ultimately concluded that 'the scientific knowledge base for toolmark and firearms analysis is fairly limited.'

Cases subsequent to these reports produce inconsistent conclusions. For example, in late 2009, an examiner in New Mexico was prohibited from testifying that his conclusion was a matter of 'scientific certainty,' yet in 2011, a Massachusetts court ruled that a trial court did not err in allowing an expert to say casings found at a crime scene were 'fired by that [defendant's] AB-10.' Some courts have attempted to resolve the problems by limiting expert testimony to terms such as 'a reasonable degree of certainty' rather than a 'match.' The problem with this approach is that studies suggest that jurors cannot distinguish between such phrases. This problem is further compounded by findings that jurors rate firearms examiners highest in terms of believability, honesty, and experience. Therefore, these supposedly more restrictive boundaries may have no practical significance at trial.

Judges May Lack the Scientific Expertise to Judge the Reliability of Scientific Evidence

Even if the procedures for evaluating scientific evidence were near ideal, judges must reign over the type of evidence admitted, the weight to give it, and the limits of expert testimony. However, judges often lack the scientific expertise to reliably judge the scientific evidence relevant to the case. In fact, recent studies show that most judges failed to understand even the most rudimentary aspects of the scientific method.

Judges, like jurors, have often sided with unreliable forensic science methods over reliable methods to the detriment of criminal defendants. The cases of Ray Krone and Deborah Green are good examples of such decision making. In 1991, Krone was convicted of murdering a female bartender who was found with a bite mark on her breast. American courts have long-accepted bite-mark comparisons (a subset of forensic

odontology) for purposes of identification. This is despite the fact that there is considerable dispute concerning the practice's value, reliability, and objectivity. Moreover, experts diverge widely in their evaluations of the same evidence. The 2009 NAS report simply concluded that there is no scientific basis for indentifying individuals by their bite marks to the exclusion of all others.

Prior to Krone's trial, an FBI odontologist told investigators that it 'could not have been clearer': Krone was *not* the donor of the bite mark. However, at trial, the state's expert testified that there was a 'definite match' between Krone's teeth and the bite mark. The state's expert was also allowed to concoct statistics on the stand: 'the possibilities of having two teeth being in the same position, it would be 150 times 150, whatever that is. May be 1200 or something like that.' Although DNA tests introduced at his second trial proved that blood found on the victim belonged to neither the victim nor Krone, Krone was again convicted on the basis of the alleged 'match' between his teeth and the bite mark. The prosecution presented no other physical 'evidence' linking Krone to the murder. Krone was exonerated by previously untested DNA evidence in 2002 after spending time on Arizona's death row.

Similarly, in 2008, Debora Green appealed her conviction for murdering her two children by setting their home on fire in 1996. The appeal was based on advances in fire science. The US District Court denied the appeal, citing the Kansas Supreme Court's opinion that placed circumstantial evidence of her motive and demeanor over that of the scientific developments in arson. Although the court heard Gerald Hurst's testimony that advances in fire science called into question whether arson could have even been the cause of the fire, the court allowed circumstantial, unscientific evidence to outweigh the scientific findings. The court found Green's casual and nonchalant demeanor and her possession of a book that depicted children dying in an intentionally set fire as sufficient evidence that Green must have committed arson.

Conclusion

In the story lines of popular television shows, cutting-edge science clears up ambiguity and leads straight to the perpetrator. Reality plays out in sharp contrast to this make-believe world. Some experts use techniques that have never been scientifically validated and others overstate their findings. In addition, judges seem ill-equipped to recognize the distinctions between reliable science and mere conjecture or to understand what limits to apply to expert opinion. Although television viewers, along with many judges and lawyers, are led to believe that scientific experts' methods can never go wrong, in some fields, the experts' methods have proven to be highly questionable. In many fields, some experts continue to give opinions without sufficient validation or proficiency testing and without any way to determine how often the experts get it right. In fact, some experts use the lack of reliability testing to support their testimony, claiming that because they have never been shown to be wrong, they have been right 100% of the time.

Law remains ill-equipped to test the reliability of scientific evidence. Law often fails to incorporate changes in science because law is beholden to finality and predictability. Judges

seem unable to recognize when experts venture outside their expertise or are unwilling to banish long-accepted but unsupported scientific assertions from the courtroom, perhaps due to fears of upsetting the criminal justice system in unpredictable ways. So like the television shows, the law demands and gets a tidy conclusion – an end of the trial where the defendant is either convicted or acquitted. Unlike the shows, however, the law does not always conclude by actually solving the crime because it continues to ignore scientific advances that would bring more reliability and less conjecture into the courtroom.

History of the Law's Reception of Forensic Science

MJ Saks, Sandra Day O'Connor College of Law, Tempe, AZ, USA

© 2013 Elsevier Ltd. All rights reserved.

Origins

The use of science in the criminal justice system was initiated for the best of reasons and the worst of reasons. Before the advent of scientific, somewhat-scientific, and pseudoscientific techniques, church and civil law-enforcement authorities relied on such varied sources as statements of witnesses (who might be mistaken or biased or fearful of telling the truth), ordeals designed to tap into God's omniscience regarding a defendant's guilt or innocence, and the interrogation of suspects using techniques that included torture in order to obtain confessions. As the US Supreme Court has noted, "We have learned the lesson of history, ancient and modern, that a system of criminal law enforcement which comes to depend on the 'confession' will, in the long run, be less reliable and more subject to abuses than a system which depends on extrinsic evidence independently secured through skillful investigation." Science thus offered not only the possibility of more accurately resolving uncertainties about who did what but also of making crime investigation more humane.

On the other hand, police agencies sometimes established crime laboratories not out of a belief in the value of scientific crime detection, but – as John Thornton, a prominent American forensic science scholar put it – as public relations gimmicks. Perhaps worse, forensic science was – and at times continues to be – used less as a tool for solving a crime and more as a means of bolstering prosecutions already undertaken against defendants targeted through more quotidian police methods.

Some of the earliest examples, however, demonstrate the potential value of bringing science to assist with problems of crime investigation and courtroom proof. In the murder trial of Spencer Cowper in England in 1699, the decedent had been found in a river. The prosecution's theory was that the defendant murdered the victim and then disposed her in the river. This factual issue could be resolved by determining whether she died before being placed into the river or died from drowning. Medical experts attempted to discover the answer by killing dogs and then submerging them in water versus killing them by drowning and then autopsying them to examine their lungs.

Some forensic sciences are adaptations of basic or applied sciences that were developed and validated in conventional scientific settings – academia or medicine or industry – and benefit from the knowledge already generated by and for those other fields. Familiar examples of those areas include identification of chemicals, microscopy, and DNA typing. At the other extreme are techniques created by and for those engaged in the investigation of crime. If science is characterized by institutionalized skepticism and systematic empirical testing to validate through rigorous efforts at falsification, then these specialties have for quite some time comprised the nonscience (or pre-science) forensic sciences. Between the two extremes, one finds

such forensic science subfields as forensic pathology, forensic psychology, and forensic anthropology.

For their part, courts have the duty to screen expert evidence for soundness. Disputes come to trial for courts to resolve based on factual evidence as well as applicable law. Valid scientific evidence is especially welcome in a rational legal world. Validity (or the law's term: 'evidentiary reliability') is the operative word.

In practice, however, courts have always had considerable difficulty carrying out that screening. A common – but not the only – pattern seen in the legal history of various fields of expert evidence is initial judicial skepticism followed by promiscuous admission, once a technique or a field has achieved a certain degree of familiarity. Perhaps the most striking illustrations of the difficulty judges have had in performing their duty to filter scientific evidence are provided by techniques that had been liberally admitted by courts for decades before other institutions (never courts) determined that those techniques lacked sufficient validity, after which courts ceased to receive them. Recent examples include comparative bullet lead analysis, voice spectrography, and a large number of arson 'indicators.'

Nothing in the usual training of lawyers and judges equips them to evaluate the claims and data (or to recognize the lack of data) of proponents of various kinds of expert evidence. The problem is exacerbated by the criminal setting (which makes judicial neutrality more of a challenge); by the Anglo-American adversary trial (which encourages attorneys to exaggerate their experts' claims); and, in the inquisitorial trials in civil law nations, by the tendency of magistrates to identify with their experts.

Making matters still worse, courts are perhaps the one setting in which science is discouraged from evolving. The great value placed on finality is constantly threatened by the possibility of scientific advances that cast doubt on techniques relied upon to reach earlier verdicts.

The history of the law's reception of forensic science is the focus of this article, primarily by courts, secondarily by other institutions. The essential questions that must be asked can be seen from the Paris prefecture of police in the 1880s, which initially hesitated to adopt Bertillon's anthropometric identification methods, to twentieth-century courts offered DNA typing: What proof of validity is required? On what basis is a technique accepted? What does it take for a technique to be found inadequate?

Legal Reception Generally

To a considerable extent, the legal reception of any proffered expert evidence should be – in addition, of course, to relevance – the product of an interaction between the rules

governing admissibility and the nature and demonstrated validity of the proffered expert evidence.

The legal reception of forensic science inevitably varies from one nation's legal system and culture to another.

In civil law countries – especially the European continent and also Asian nations, such as Korea – investigating judges appoint experts of their choosing, typically one from a predetermined list, and typically, the judge accepts the conclusions of the expert. Thus, the court already regards the underlying expertise as valid and the expert competent in that expertise. The civil law system provides little room for questioning the soundness of the expertise or the competence of the expert, compared to Anglo-American legal process, where challenges are readily accommodated. On the other hand, experts in civil law systems are employed by and identified with the court rather than with the prosecution. So, for well-validated areas of expertise, the risk of bias and fraud is lessened. In adversarial arrangements, bias and fraud are not only more possible but also, theoretically, more subject to exposure.

For centuries, Britain's regulation of expert testimony has not become more rigorous than several general common law requirements: 'assistance,' 'relevant expertise,' 'impartiality,' and 'evidentiary reliability.' The Law Commission in 2011 recommended a statutory rule that would require courts to determine whether proffered expert evidence was sufficiently reliable to be admitted, which would require the evidence to be "predicated on sound principles, techniques and assumptions," and that those principles, techniques, and assumptions be properly applied to the facts of the case.

The most extensively developed rules governing the admission of expert testimony have emerged in the United States. Our discussion will emphasize those rules and cases decided under them.

Legal Control over Admission of Expert Evidence

While the commonsense meaning of an expert is a person having comprehensive and authoritative knowledge or skill in a particular area, the legal meaning is both less demanding and more specific. An expert in court is a person who is permitted to give an opinion (draw an inference) on an issue which other persons (judges or jurors) would not be able to do competently. The law's focus is on the contribution the expert witness is intended to provide in the trial.

Any legal test for filtering expert evidence must confront a fundamental contradiction: if expert evidence is needed because nonexperts lack the knowledge necessary to reach sound conclusions on a subject, how can nonexperts be competent gatekeepers of the proffered expert evidence, or be able to properly assess admitted evidence? To avoid being misled by expertise the factfinder cannot adequately evaluate, the law seeks to filter out unsound expert evidence.

Over the past century and a half, American law has tried in various ways to develop criteria for evaluating proffered expert evidence.

Qualifications

One early evaluation method relied on the 'qualifications' of a proposed expert. A witness who had the necessary education,

training, or experience could be accepted as an expert – though how much education-training-experience sufficed has never been specified. Courts eventually came to recognize that the qualifications of the proposed expert was a separate question from the validity of an expertise. An additional question had to be answered: does a valid expertise exist? Only if a valid expertise exists can one sensibly ask whether the proffered expert is qualified to share that field's knowledge with the court.

Marketplace Test

Courts in the nineteenth century can be seen to evaluate experts and their expertise by considering the proposed expert's commercial success in his field. The inference is that if a proffered expert's knowledge and skill are in demand by private paying customers who need such expertise, then the court can also rely on that skilled witness. Thus, the court's evaluation method was to look at the market's evaluation of a proposed expert.

Frye Test

The test articulated by *Frye v. U.S.* in 1923 is a variant of the marketplace test. Faced with an early polygraph test – for which there was not yet a private market – the court substituted an intellectual market for a commercial market. Admission was conditioned on the requirement that the "thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs." Whereas the marketplace test designated consumers as the practical judges of the value of an asserted expertise, the Frye test shifted that task to producers of the asserted expertise. The Frye test was largely ignored for close to half a century, but came to life in the years leading up to the adoption of the (US) Federal Rules of Evidence – years during which the contemplated codification was being researched, debated, and drafted.

Daubert Trilogy

The US Supreme Court held in *Daubert v. Merrell Dow Pharmaceuticals* in 1993 that the Frye test had been displaced by the Federal Rules of Evidence. The test that emerged from *Daubert* requires that to be admissible empirically based expertise must satisfy essentially the criteria of empirical science: that it be testable, that it be tested using sound research methodology, that the findings support the field's claims about the expertise, and that adequate standards be maintained in the application of the principles to the task at hand. These requirements apply to long-admitted as well as novel types of expert evidence. In *General Electric v. Joiner*, the Supreme Court held a trial judge's decision to admit or exclude was reversible on appeal only as an abuse of discretion – meaning that almost any admission decision would stand, and appellate courts may not develop case law to guide lower courts. In *Kumho Tire v. Carmichael*, the Supreme Court held that *Daubert* was to be understood as standing for the proposition that all forms of expert evidence – not only those denominated science – must be demonstrated to be valid, sound, dependable if the

testimony is to be admitted. Moreover, the court held that general acceptance by itself was insufficient to justify admission.

Reception of Science-Based Forensic Sciences and Semi-Science-Based Forensic Sciences

Centuries ago, courts were admitting expert testimony on topics of medicine, microscopy, chemistry, and other matters that today would be regarded as incomplete or incorrect. When it occurred at all, screening was less than rigorous. Over time, the knowledge base of those fields improved through advances in testing, technology, new empirical findings, and new theoretical understandings. Indeed, they evolved into *fields*, with the institutional advantages that a variegated community of workers brings to the challenges of building, testing, and rebuilding a field's knowledge.

With testimony of more primitive forms of knowledge from those fields already being admitted, advances that came to replace the earlier knowledge would almost inevitably be regarded as admissible, *a fortiori*. Though newer knowledge based on different methods is, in principle, subject to careful judicial evaluation, rarely would such scrutiny be interposed. The knowledge of these fields, therefore, was 'grandfathered' in (again and again) and subjected to little judicial scrutiny.

Medicine/Pathology

By 1248, the first treatise on forensic medicine had been published, in China, by HsiYüan Lu. As is true today, the principal focus was on cause of death. Among many other questions, HsiYüan Lu's book advised on how to discern whether a body found in water had drowned or was killed first and then placed in the water. The scope of legal medicine included public health issues and insanity, as well as the resolution of suspicious deaths, including unexplained infant deaths (pursuant to a 1624 English statute). In the United States, any doctor could opine on the cause of death, and on countless other issues. The courts imposed no special qualifications or other requirements. Greenleaf, whose life spanned the years 1783–1853, stated in his respected treatise on evidence law: "The opinions of medical men are constantly admitted as to the cause of disease, or of death, or the consequences of wounds... and as to other subjects of professional skill."

Identification of Skeletal Remains

When skeletal remains are found in the course of a search for a missing person, or are stumbled upon unexpectedly, investigators ask whether what has been found is human or animal, and, if human, what features might be inferred of the person whose remains these are. For centuries, opinions on these matters were provided by physicians and later by students of anatomy. With rare exceptions, anthropologists were not considered by courts to be experts on skeletal remains until the latter half of the twentieth century. Perhaps the first occasion was when George Dorsey, an anthropologist at the Field Museum in Chicago, testified as an expert in the second trial of Adolph Luetger for the murder of his wife in 1897. Dorsey

opined on the identity of the bone fragments, and a conviction resulted. The testimony contained a degree of precision that would later be considered unsupportable on the evidence and the available science. Forensic anthropology has since been quite attentive to the limitations on opinions that can be reached as a function of the nature and quantity of the remains recovered.

Chemistry

The identification and quantitation of substances, as well as analysis of changes in substances, are made possible by the application of techniques derived from basic knowledge in chemistry. At any given point in history, investigative and adjudicative organizations have been able to draw on witnesses with knowledge of chemistry at whatever the state of its art has been – from primitive techniques in use centuries ago to modern tools and techniques, including ultraviolet, infrared, and visible spectrophotometry; neutron activation analysis; gas chromatography and mass spectroscopy; liquid chromatography; and atomic absorption spectroscopy. Forensic chemistry has evolved along with advances in basic and applied chemistry in use in academic, medical, and industrial settings. Forensic chemistry has been of far-reaching value to the law in both civil (e.g., regulation of the quality and safety of food, drugs, and other products; in environmental litigation) and criminal matters. Its contribution to the latter includes comparison of known and questioned samples of trace evidence such as fibers and paint chips, analysis of inks and papers of questioned documents, visualization of latent fingerprints, measurement of color of microscopic glass fragments, detecting the presence of and measuring alcohol and drugs, determination of blood group to which a person belongs (conventional serology), major aspects of DNA typing, and toxicology (the latter two will receive separate attention in the paragraphs below).

Toxicology

One of the more familiar factual issues in suspicious death cases over the centuries has been whether a death was natural or caused by poisoning – an issue that crosses chemistry with medicine. Countless experts have offered their opinions in cases raising such questions, and legitimate controversy not infrequently accompanied their opinions. In many sensational poisoning trials, doctors and chemists offered novel tests for detecting the presence of poisons, though some of the tests had not yet been validated and others never would be. The courts were long unclear on what knowledge was needed to opine dependably on whether a substance (of a given dosage) could cause death, and who might possess that knowledge. Of course, 'medical men' were permitted to opine. So might chemists or apothecaries. In time came persons purporting to be learned specifically in the signs and effects of poisons, that is, toxicologists. The courts did not look much at what empirical evidence supported the claimed knowledge, that is, at the science of the topic, but tended to focus on the witness's 'experience' or the guild to which the expert belonged, and whether it was one that judicial common sense suggested that they ought to know about such things. As late as 1872, a court

in the United States ruled that no expert at all was needed to determine whether a drug that was capable of causing death was administered.

DNA Typing

In several important respects, DNA typing's history contrasts sharply with that of other forensic sciences. Unlike other specialties that made claims to being able to individualize sources of evidence (such as fingerprints, toolmarks, handwriting, and so on), to be discussed below, DNA typing is the only one that was grounded in existing, extensive scientific knowledge. DNA typing arrived in the late 1980s as something new, unburdened by expert witness ancestors offering similar opinions on the strength of more primitive science. It was developed after (and from) more basic science that provided its foundation – molecular biology and population genetics (statistics) – which had already been well developed in settings where science dominated and the demands of litigation were all but unknown. This meant that courts were forced to view it with clearer eyes and without the tendency to grandfather in new versions of old kinds of experts (discussed earlier). It also meant that a large number of scientists and statisticians were in a position to assist in subsequent debates over the soundness of its many aspects, from the most basic to its forensic applications. Initially, courts admitted testimony on DNA typing without challenge. But, soon, questions arose, a series of 'DNA wars' ensued, and some courts refused to admit DNA typing. The debates took place not only in court but, importantly, in journals, in scientific conferences, and in two successive panels of the (US) National Research Council. The debates exposed flaws and facilitated the development of solutions. There is now widespread agreement that this process – and the availability of numerous highly competent scientists to assist those attacking and defending each issue – has led to a far sounder and more widely accepted set of techniques. As one commentator has put it, 'DNA is a strong discipline today in part because courts reviewed it rigorously at the outset. The discipline underwent a trial-by-fire that exposed genuine problems and forced proponents to correct weaknesses.'

Reception of Individualization Claims

To learn that courts and other legal institutions welcomed the best science of their era – or even an imperfect copy of that science – tells one little about the capacity of legal institutions to distinguish sound science from poor science or pseudo-science. In general, it appears that the legal system is not equipped to draw the distinction. As a landmark report of the (US) National Research Council stated, referring to the sub-fields to be discussed in this section: "Forensic science professionals have yet to establish either the validity of their approach or the accuracy of their conclusions, and the courts have been utterly ineffective in addressing this problem." With important exceptions and despite legal rules which, if applied conscientiously, would produce more restrictive rulings, the general practice for admission of all forensic science expert testimony has long been a liberal one.

The subsections below provide a more detailed discussion of the courts' responses to proffers of forensic specialties that fall into the category of what might be termed the traditional, pattern comparison, individualization forensic sciences.

Handwriting Identification

Handwriting identification is the oldest of the currently active forensic sciences. The notion that handwriting can be used to identify an author can be found as far back as Aristotle. Attempts to develop a system of such expertise started in Italy and France in the 1600s and by 1737 were well enough accepted in France to have been incorporated into the law. A century later, handwriting expertise entered Anglo-American courts, although the courts welcomed it hesitantly, more often excluding or placing limitations on the expert than simply allowing the testimony. Not until an 1854 statute was construed to authorize it did handwriting identification expertise become admissible in English courts.

In the United States, until passage of the English statute, most American jurisdictions followed English practice and rejected such expertise, though there were important exceptions. In 1836 Massachusetts became the first common law jurisdiction to authorize the use of handwriting experts. By 1900 a substantial majority of American jurisdictions allowed such testimony, but usually still with skepticism.

Two events finally gained respectability for handwriting expertise. One was the publication in 1910 of Albert S. Osborn's *Questioned Documents*, with an introduction by John Henry Wigmore. Wigmore's endorsement of his friend's book, as much as the book, helped establish the field's respectability in the eyes of lawyers and judges.

The second event establishing the acceptability of handwriting examiners was the Lindbergh Baby kidnapping case in 1935. Osborn was the chief witness called to testify that Bruno Richard Hauptmann had written all of the ransom notes found or sent after the child's abduction. For 60 years following the affirmance of *State v. Hauptmann*, no reported opinion rejected handwriting expertise, nor was much judicial skepticism expressed. After standing unquestioned for most of the twentieth century, a re-evaluation of handwriting identification expertise resulted from the US Supreme Court's decision in *Daubert*, and the re-evaluation continues. Often, the proffered expertise goes unchallenged. When challenged in a serious way, courts have excluded it entirely, admitted without limitation, or, most often, admitted with limitations. The most common limitation is to allow descriptive testimony but to prohibit the expression of conclusions of authorship, an approach first used in *U.S. v. Hines* in 1999. The court in *U.S. v. Starzecpyzel* in 1995 observed that, "the testimony at the *Daubert* hearing firmly established that forensic document examination, despite the existence of a certification program, professional journals and other trappings of science, cannot, after *Daubert*, be regarded as 'scientific . . . knowledge.'"

Fingerprints

The history of the use of fingerprints for identification has been traced back to ancient Babylonians and Chinese, though it was not until the nineteenth century that they appear to have

been used systematically for identification in criminal cases. Although Sir Francis Galton did the first serious scientific work on variability in fingerprints, publishing his treatise, *Finger Prints* in 1892, when asked about the subject he cautioned the British government that he did not believe fingerprints were dependable enough for use in linking crime scene latent prints to their source.

Notwithstanding such cautions, and despite a continuing lack of scientific support for the extreme claims required to conclude unerringly that a given individual was the only possible source of a latent print, today, expert testimony on fingerprint evidence is admitted everywhere.

The first English case upholding admission of fingerprint expert testimony linking a defendant to a crime was *R. v. Castleton* in 1909. Case law in the United States upholding admission of fingerprint expert evidence began in Illinois in 1911 with *People v. Jennings*. Within a decade, New Jersey, New York, Nevada, and Texas joined in approving the admissibility of fingerprint evidence and by the end of the 1930s all but five states had done so.

These courts invested little effort assessing the merits of the proffered expert evidence. For example, in upholding the admissibility of fingerprint expertise, the Jennings court cited several general books on crime investigation, the Castleton case, and four witnesses. Nowhere did the court articulate the basis of the expertise it was evaluating, or discuss any scientific data bearing on the empirical claims. In conclusory fashion, the court held simply that, "there is a scientific basis for the system of finger print identification, and that the courts are justified in admitting this class of evidence. . . ."

N.Y. v. Roach did no more than to cite Castleton and Jennings. The opinion offers no citations to any scientific materials or any discussion of the principles claimed to be the foundation of the technique. The quality of judicial scrutiny of fingerprint evidence rarely exceeded that of Jennings, and sometimes it fell much shorter.

In the wake of Daubert, dozens of hearings have been held to re-evaluate the admissibility of fingerprint expert evidence. In virtually every one of those cases, the courts held the testimony admissible without limitation – though not one of those opinions was able to explain how the proffered testimony actually satisfied the law's requirements. Instead, the opinions found ways around Daubert, creating what one commentator termed 'a catalog of evasions.' Among these were substitute trial processes for scientific evidence, rely entirely on general acceptance, relieve proponent of the burden of proof, and lower standards as necessary to allow the asserted expertise to satisfy them.

In contrast, some fingerprint experts grew more sober about what their field could establish scientifically. In comparing what the courts required of DNA typing, one commented: 'Woe to fingerprint practice were such criteria applied!'

Toolmarks

Toolmark examiners compare markings left by various kinds of tools to try to determine which tool (to the exclusion of all others in the world) left its marks at a crime scene.

One of the earliest appellate decisions to consider the admissibility of toolmark identification was *State v. Fasick*, a

1928 Washington State case which rejected the proffered testimony. In that case, a murder had been committed and the body covered with fir branches cut from nearby trees. The government offered Luke May, one of the founders of toolmark identification. May had made sample cuttings of fir branches with the suspect's knife and examined microscopic marks left by the blade, comparing them with the marks left in the branches found covering the body. He concluded that the crime scene branches had been cut with the defendant's knife. The Washington Supreme Court found the logic behind the expert's opinion unconvincing and held that admitting the testimony had been an error. On rehearing a year later, the court affirmed its rejection of toolmark identification expertise.

But only 6 months after reaffirming itself, the same court was presented with remarkably similar evidence in *State v. Clark*, in the context of a rape case in which fir boughs and saplings had been cut and used to construct a blind from which to attack the victim. But this time the court held that expert opinion about whether the defendant's knife cut the branches was admissible: 'The photomicrographs. . . conclusively establish, we are convinced, as doubtless the jury were, that the cuts were made with the same blade.' There is little if anything in the Clark opinion that could help a judge in a subsequent case to understand why claims about a science of toolmark identification were valid. The case merely offered the conclusory and unexplained enthusiasm of a court that only months before had rendered an opposite opinion on the same question. Both the exclusion of the purported science in *Fasick* and its admission in *Clark* are unexplained.

In the decades since, the subject of the validity of toolmark identification evidence came in for surprisingly little appellate examination. Only recently have some courts circumscribed ballistics evidence, precluding individualization or barring use of terms such as scientific certainty. Overall, however, there has not been serious judicial evaluation of the validity of the underlying science or its application to the tasks at issue in the cases.

Voiceprints

The basic assumption of 'voiceprint' identification is that each person's vocal apparatus is unique and therefore the voice sounds produced are unique. By converting voice sounds to a visual display using a sound spectrograph, the examiner can compare tracings of questioned and known voices and determine the identity of the source of the questioned voice.

Judicial opinions on the admissibility of such expertise, beginning in the late 1960s, have been widely divided: about as many courts admitting as excluding. No consistent or coherent judicial view ever evolved and now voiceprint identification in the United States has become essentially a dead letter. The birth, development, and death of voice spectrography in American courts provide an instructive history.

First, one might expect that when a new expertise is proffered, the courts would at first be divided in their views, and over time converge on a shared view. The pattern, however, showed no greater agreement among courts in the latter years than there had been in the early days of voice spectrography.

Second, it is evident to a remarkable degree that the legal test of admissibility applied by the courts is highly correlated

with the holding. Of the courts applying the Frye test in a broad fashion – that is, treating the relevant scientific community as consisting of a range of relevant fields (acoustical engineering, physics, statistics, linguistics, etc.) in addition to the narrow group of practitioners who performed the examinations—every single case excluded the proffered testimony. Of courts applying the Frye test narrowly (narrowing the relevant field to practitioners), every one admitted the testimony. These two outcomes illustrate one of the important criticisms of the Frye test, namely, that defining the relevant scientific fields broadly or narrowly often dictates the admissibility conclusion.

In recent times, when voiceprint evidence is proffered, now under Daubert, it usually is by defendants; the government opposes admission; and in the courts exclude.

Why was voiceprint expert evidence never admitted as routinely as other forensic techniques? A vigorous literature relevant to voice spectrography existed, giving judges far more information than they have seen regarding earlier forensic individualization techniques. This immediately provided the courts with unaccustomed resources with which to comprehend the imperfections of the technique. By providing rigorous empirical self-evaluations of its own concepts and methods, a field aids the courts in making more informed assessments.

Bitemark Identification

In trying to identify perpetrators of crime, the forensic odontologist compares a suspect's dentition with a bitemark left in a victim's flesh or some other substance found at the crime scene.

Forensic odontologists had long been involved in identifying victims of plane crashes and other disasters using dental records and the actual teeth of disaster victims. But they were doubtful that the state of their knowledge would permit the more challenging task of identifying the source of a partial bitemark in skin. Despite those doubts, when their testimony was offered to courts, the courts readily admitted the testimony.

The cornerstone case on the admissibility of bitemark identification was decided in California in 1975 in *People v. Marx*. At trial, three expert witnesses testified to their opinion that the defendant's dentition matched the bite wound. One of those experts explained that in many other cases he had refused to offer an opinion of identification. This case, however, was an exception because the dentition at issue was highly unusual and the bitemark was exceptionally well defined. Despite the experts' caution and the unusual nature of both the dentition and the bitemark, once the courtroom door was thrown open, Marx became the precedent for admitting a far wider and more dubious array of opinions in many subsequent cases.

On appeal, the court acknowledged that there was 'no established science of identifying persons from bite marks. ...' The court of Appeals deflected the implications of Frye by interpreting that test to apply only to evidence that was indecipherable without expert interpretation, whereas Marx involved images that were plainly available for the jury to view and interpret on their own. So, on the court's view, the Frye test was inapplicable.

Alternatively, the court concluded that Frye's requirements had been met because the methods used to visualize the dentition and bitemark were not novel. There is nothing new

about X-rays, photographs, casts, and so on. In this view, Frye is about tools, not the theory of identification or the interpretation of the information made visible with the help of those tools.

Finally, the Marx court believed that evidence on or thoughts by the expert about the probabilities underlying bitemark identifications would be inadmissible in California under *People v. Collins*. But since the experts never had actual data and therefore did no calculations on data, but instead remained impressionistic and intuitive, the law was satisfied. 'None of the witnesses engaged in a "trial by mathematics" on or off the stand.'

The following year, Illinois had its first occasion to consider the admissibility of bitemark evidence. In *People v. Milone*, the Court of Appeals held it admissible as meeting the general acceptance test notwithstanding trial testimony citing odontological literature showing considerable disagreement among forensic odontologists as to whether biters could be uniquely identified from bites left in the flesh of victims.

From those cases until Daubert, and even after Daubert, little that is new has emerged in judicial thinking concerning bitemark expert evidence. Admission has spread throughout the United States.

The most noteworthy developments are the cases of persons wrongfully charged or wrongfully convicted on the basis of bitemark identifications, and later exonerated by DNA or other evidence: Bourne in Mississippi, Krone in Arizona, Brewer in Mississippi, Burke in Massachusetts, Gates in Mississippi, Morris in Florida, Otero in Michigan, Young in Illinois, and others. Some of these individuals were imprisoned for two decades before the error was corrected.

In each of the DNA exonerations, a forensic dentist had earlier opined that the defendant was the one and only person in the world who could have made the bitemarks; later it became clear that the forensic dentist was incorrect. Nonetheless, there was no judicial rejection of the general reliance on such testimony.

Lessons of Legal History for Future Law–Forensic Science Interaction

From the preceding discussion, some generalizations might be drawn about the history of the law's reception of forensic science, as well as a glance into the future. Most forensic science techniques were accepted by the criminal justice system, including the courts, with little if any rigorous testing of validity by those institutions. The earlier in time a given field was invented and introduced, the more true that appears to be; later courts simply continued on the path begun by the earliest courts to meet a field. As a result of those patterns, sometimes fields that were more soundly based (e.g., DNA typing) were scrutinized more carefully than fields that were far weaker but older. Courts displayed little capacity to assess the validity of empirical claims. As far as possible, they sidestepped their evidence-screening responsibilities, and presumed validity, notwithstanding the requirements of the law governing admission of expert evidence. Fields that turned out to be so flawed that they have been removed from the catalog of forensic science offerings were treated with as much credulity by the courts as any other proffers of forensic evidence.

Whether courts will become more engaged in supervising the forensic science evidence that comes before them remains to be seen. But pressures to improve have been mounting, especially in the United States and in other nations as well. A recent study of US courts suggests that such change is taking place. That study found that, in the wake of Supreme Court decisions on judicial gatekeeping of expert evidence, in cases where the admissibility of forensic science evidence was challenged, courts excluded or limited testimony 15% of the time, 'largely because of a failure to demonstrate a sufficient scientific foundation for either the technique (27 cases) or the expert's conclusions (17 cases).' The two subfields that accounted for most of these exclusions and limitations were handwriting identification and firearms and toolmark examination. The study concluded that, 'The incidence of exclusion/limitation because of a lack of demonstrable reliability suggests that there is a continuing need for the forensic sciences to pursue research validating their underlying theories and techniques of identification to ensure their continued acceptance by the courts.'

Another possible source of change might be the provision of experts to parties other than the government – in most instances, defendants in criminal cases. More ready availability of consulting (even if not of testifying) experts for one side to scrutinize the proffered expert evidence of the other side would be expected to expose otherwise invisible problems in the underlying science or its applications, and especially in applications to particular cases. In the United States, the legal source of a potential right of criminal defendants to the assistance of experts is found in the 1985 Supreme Court case of *Ake v. Oklahoma* (holding that a defendant had a due process right to the assistance of a psychiatric expert in a capital case where the defendant was offering a defense of insanity). Whether defendants in noncapital cases, seeking the assistance of experts other than psychiatrists, are protected by the rights recognized in *Ake* has not yet been addressed by the high court. Lower courts have interpreted *Ake* in quite different ways. As one scholar who has reviewed the state of the law has summarized, 'some courts give a cramped reading of *Ake* to limit its scope, while others appreciate that the opinion cannot be so easily cabined.' The great power and importance of forensic expert evidence cuts both ways: its power suggests a commensurate need of the defense to have similar expertise at their disposal, and its importance suggests that the exercise of this right will be frequent and therefore costly. Recent events, notably the (US) National Research Council's report on the scientific weaknesses of a number of the forensic sciences, might lead judges to grant defense requests for experts more often, and those experts will in turn bring more problems to the attention of courts, leading forensic scientists in crime laboratories to do the foundational research that has been lacking.

The future might or might not be different from the past. The re-evaluation of forensic evidence is a continuing and potentially evolving process. The interaction of law and science is at its greatest with forensic science, because the forensic sciences have the courts as their ultimate customer. Consequently, the decisions of the courts can have more impact on the forensic sciences than it could have on other fields. If courts were to demand more, the forensic sciences almost certainly would deliver more.

International Courts and Forensic Science

X Laroche, Special Tribunal for Lebanon, Leidschendam, The Netherlands

E Baccard, International Criminal Court, The Hague, The Netherlands

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Admissibility The question whether particular forms of information may be submitted to a Court as formal evidence, the question being answered by reference to the exclusionary rules of evidence and practice developed within the legal system.

Exhibit Term used to describe an item presented in a court trial as part of the evidence.

Extraordinary Chambers in the Courts of Cambodia (ECCC) Further to an agreement concluded in June 2003 between the Royal Government of Cambodia and the United Nations (UN), the ECCC was created for the prosecution of crimes committed during the period of democratic Kampuchea. Cambodia invited international participation due to the weakness of the Cambodian legal system and the international nature of the crimes, and to help in meeting international standards of justice.

International Criminal Court (ICC) The ICC, created and governed by the Rome Statute and entered into force on 1 July 2002, is the first permanent, treaty-based international criminal court which was joined by 121 countries (effective as of 1 July 2012) and was established to help end impunity for the perpetrators of the most serious crimes of concern to the international community, that is, genocide, crimes against humanity, and war crimes. The Court shall exercise jurisdiction over the crime of aggression once a provision defining the crime and the conditions for the exercise of jurisdiction enter into force. The Court acts only when the countries themselves are unable or unwilling to genuinely investigate or prosecute Rome Statute crimes. The ICC, based in The Hague (The Netherlands), is an independent international institution and is not part of the UN system.

International Criminal Tribunal for Rwanda

(ICTR) Recognizing that serious violations of humanitarian law were committed in Rwanda and acting under Chapter VII of the UN Charter, the Security Council created the ICTR by Resolution 955 of 8 November 1994 for the prosecution of persons responsible for genocide and other serious violations of international humanitarian law committed in the territory of Rwanda between 1 January 1994 and 31 December 1994. The seat of the ICTR is Arusha (Tanzania) and the Tribunal has an office in Kigali (Rwanda).

International Criminal Tribunal for the former Yugoslavia (ICTY) The ICTY is an ad hoc court based in The Hague (The Netherlands) and was established by the UN Security Council Resolution 827 of 25 May 1993 for the prosecution

of persons responsible for serious violations of international humanitarian law committed in the territory of the former Yugoslavia since 1991. It has jurisdiction over four clusters of crime committed in the territory of the former Yugoslavia since 1991: grave breaches of the Geneva Conventions, violations of the laws or customs of war, genocide, and crimes against humanity.

ISO (International Standards Organization) An international nongovernmental body that develops and publishes guides and standards for quality practices and procedures.

Persistence In the context of trace evidence, persistence relates to the length of time trace evidence remains as an item following a transfer event. Persistence is a property of both the material transferred (donor) and the item onto which transfer has occurred (recipient). Persistence may also be influenced by the nature of the transfer and by external factors.

Scene of crime officer An investigator skilled in recognition, preservation, and collection of trace and other evidence from a crime scene.

Special Court for Sierra Leone (SCSL) The SCSL was set up jointly by an agreement between the Government of Sierra Leone and the UN for serious violations of international humanitarian law and Sierra Leonean law committed in the territory of Sierra Leone since 30 November 1996.

Special Tribunal for Lebanon (STL) On 13 December 2005, the Government of the Republic of Lebanon requested the UN to establish a tribunal of an international character to try all those who are allegedly responsible for the attack of 14 February 2005 in Beirut (Lebanon), resulting in the death of former Lebanese Prime Minister Rafik Hariri and in the death or injury of other persons. The Tribunal's jurisdiction may also extend beyond the 14 February 2005 bombing if it finds that other attacks that occurred in Lebanon between 1 October 2004 and 12 December 2005 are connected in accordance with the principles of criminal justice and are of a nature and gravity similar to the attack of 14 February 2005.

Weight of evidence In contrast to the admissibility of evidence, a question of law, the weight accorded to such evidence is a question for the finder of fact. A judge may admit scientific evidence; however, the finder of fact will decide the weight to be accorded to such evidence, that is, whether or not such evidence is credible or reliable.

The views expressed herein are those of the authors alone and do not necessarily reflect the views of the Special Tribunal for Lebanon or the International Criminal Court.

Even though the origins of forensic science can be traced to the sixth century in China, modern forensic science originated in the late nineteenth century and as the field expanded, its application to legal issues became more and more common and now, most national law enforcement agencies operate crime laboratories that perform scientific studies of evidence.

In the meantime, many international courts have been created in the last decades and international prosecutors have been given a mandate to investigate and prosecute those responsible for the world's most serious crimes.

In some cases before the international criminal tribunals, forensic science plays a central role, notably related to crime-based evidence. In other cases, evidence of the criminal incident is largely undisputed; what is in dispute is the connection between that incident and the accused, who may be a high-level political leader. That linkage is normally made through documentary, rather than forensic, evidence.

Nevertheless, most international criminal trials contain at least an element of forensic evidence. Forensic science has increasingly become a very useful tool and each international criminal tribunal has more or less developed forensic investigations. If access to crime scenes and their protection improve, and if investigators gain access to crime scenes relatively quickly after the alleged crime, it can reasonably be expected that forensic evidence will play an increasingly important role in international courts. In addition, many challenges, both scientific and legal, are limiting the efficiency of forensic science within international criminal tribunals. Many improvements could be made to ensure that forensic science is exploited to its full potential and is able to achieve much more in the future for the benefit of fair and impartial trials at international criminal tribunals (ICTs).

The Current Contribution of Forensic Science to the ICTs

International Criminal Tribunals

Establishment of international criminal tribunals

The idea of setting up international criminal tribunals emerged after the First World War, but the first of such tribunals could be seen only after 1945 with the establishment of International Military Tribunals in Nuremberg and Tokyo. Subsequently, the United Nations (UN) system started the process to dispense international criminal justice more permanently and impartially in the late 1940s by trying to codify international crimes and elaborate a draft statute for the establishment of an international court.

However, only in the 1990s were ad hoc international criminal tribunals established, limited both temporally and geographically for specific conflicts: in 1993, the International Criminal Tribunal for the former Yugoslavia (ICTY); and in 1994, the International Criminal Tribunal for Rwanda (ICTR). On 17 July 1998, and under the agreement that an independent and permanent criminal court was needed, 120 states adopted the Rome Statute, the legal basis for the establishment of the ICC, which entered into force on 1 July 2002 after ratification by 60 countries.

In recent years, nations have also established mixed courts, the statutes and rules of which combine aspects of

international and national law, to respond to emergency situations involving large scale atrocities: mixed courts have been established for East Timor (2000), Kosovo (2000), Sierra Leone (2002), Cambodia (2003), Bosnia and Herzegovina (2005), and Lebanon (2007). Their first goal is to hold individual perpetrators accountable for the crimes they have committed and to punish them in accordance with a system of international criminal justice, which is essentially adversarial (differing from other national jurisdictions that use an accusatorial system).

Crimes prosecuted by international criminal tribunals

ICTs deal principally with war crimes, crimes against humanity, and genocide. More recently, the Special Tribunal for Lebanon (STL) has been given the mandate to prosecute what is essentially an act of terrorism: the attack that killed the former Lebanese Prime Minister Rafic Hariri on 14 February 2005 in Beirut.

In most cases, international courts rely to some extent on forensic science to establish the *actus reus* of an atrocity crime. For certain crimes, there exists an additional element, victim identity, where forensic evidence is of relevance. Genocide law affords protection to only four groups of victims, those having the same ethnical, racial, religious, or national identity. And forensic science, mainly through forensic anthropology, has been helpful in proving this element.

The role of forensic science

The role of forensic science within international criminal tribunals is the same as at national levels, that is, to provide information to help answer questions of importance to investigators and to courts of law. This can be simply factual, and therefore noncontentious, or it may take the form of an expert opinion through an inferential process. Within international criminal proceedings, the forensic scientist is requested to provide the court with three types of forensic science opinion: investigative opinions, preliminary evaluative opinions, and fully evaluative opinions.

At the moment, only the ICC and the STL have a full-time forensic team supervised by a forensic coordinator.

Crime Scene Investigations at ICTs

There are three main problems related to the collection of forensic evidence in ICTs

1. *Crime scenes within conflict zones.* The area where the crimes occurred may still be an environment of conflict and the crime scene investigations are obviously logistically much more complicated than in times of domestic tranquillity. Additionally, crime scene investigation is often made more difficult as several attacks may have occurred in the same area in a relatively short period of time and attributing evidence to a specific event may be more than challenging.
2. *Restricted and late access to crime scenes.* In postconflict environments, access to crime scenes typically becomes available months or years after the crimes have been committed. This is, in part, due to securing a legal right of access: international investigators lack the power to enter and/or remain upon the territory of any state without the consent

of that state's government, or a mandate from the UN Security Council. Related thereto is the long process required for an international investigation to be set up. This makes the collection of forensic evidence extremely difficult. For instance, decomposition of soft tissues will render the visual identification of the remains quite difficult, making other techniques such as forensic odontology or DNA all the more important. Items of evidence, such as cartridge cases, shrapnel, or victims' clothing, may be lost, having been collected by local inhabitants. The site itself may have been rehabilitated because of lack of local infrastructures, with cleaning (bloodstains), plasterwork, and painting (bullet impacts), or even rebuilt (burnt/bombed buildings).

In a best case scenario, the international team can benefit from the results and outcome of the crime scene investigations conducted by local authorities, but along with all the problems inherent to this. Even where an investigative mission is dispatched relatively quickly, it is possible that physical evidence may have been tampered with, or destroyed, or may have physically deteriorated or disappeared altogether.

3. *Reliance on the cooperation of states.* If the states where investigations must be carried out are not cooperative, the collection of forensic evidence is very difficult technically and logistically, and the safety of international investigators and the integrity of the investigation may be jeopardized. Even where the nation is cooperative, poor local technical resources and the lack of forensic infrastructures can sometimes constitute an obstacle, a problem compounded by the distance between the scene of the investigation and the court.

The Use of Forensic Evidence by International Criminal Tribunals

The Statute and Rules of international criminal tribunals set out, with more or less precision, principles for the collection of evidence and principles governing when evidence presented at court will be admitted versus excluded.

Collection of evidence

The gathering of evidence in international criminal tribunals is based on the adversarial or accusatorial model, where parties, for example, the prosecution and the defense, gather and present the evidence and their arguments to judges who know nothing of the litigation.

In addition, courts are not completely bound by strict and technical rules of evidence. This concept found expression in Article 19 of the Charter of the International Military Tribunal (Nuremberg): "The Tribunal shall not be bound by technical rules of evidence. It shall adopt and apply to the greatest possible extent expeditious and nontechnical procedure, and shall admit any evidence which it deems to have probative value."

There are three types of rules for the collection of physical evidence through searches and other on-site investigations by international prosecutors at the ICC and ad hoc tribunals:

Power-based rules: According to the Statutes of the ICC or ad hoc tribunals, the prosecutors have the right to collect evidence

on the territory of states, but the powers of the prosecutors to do so differ greatly, in particular, their ability to use their own staff to carry out on-site investigations.

The ICC prosecutor can carry out on-site investigations using his own staff instead of state authorities on a state party's territory: (1) where the state consents; (2) where the Pre-trial Chamber has determined that the State is clearly unable to execute requests for cooperation; or (3) where certain additional conditions exist, warranting the execution of investigative activity without any compulsory measure. If none of these exceptions apply, the ICC prosecutor may request the state to carry out on-site investigations on his behalf or with the participation or presence of his investigators. The states that are not party to the Rome Statute are not obliged to cooperate with the Court unless as members of the UN they are required to cooperate by the UN Security Council.

Prosecutors at ad hoc tribunals have a general statutory power to collect evidence and conduct on-site investigations on the territory of UN member states, without an obligation to seek the state's assistance. Prosecutors at ad hoc tribunals are able to request a state's cooperation, which can further be ordered by the court's judges. This mechanism of requests for assistance has been widely used by the STL Prosecutor. They can, therefore, bypass the state authority and seek that a search warrant, for instance, be issued directly by a trial chamber. Even where the trial chamber issues a search warrant, in reality, it is possible to execute the warrant, in the absence of state consent, only where the territory is under the control of international forces.

Although these legal frameworks would suggest that the ad hoc prosecutors are in a much better position than the ICC prosecutor in regards to evidence collection, the practical implementation is different and the ICC and ad hoc tribunals face the same problems in convincing states to render assistance with the collection of evidence.

Other problems occur when international forensic experts have to deal with national authorities: problems of mutual confidence, scientific knowledge and standards, forensic equipment, and facilities.

Right-based rules: A key right of a witness or a suspect is the right to privacy. Even though this right to privacy is not expressly mentioned in the ICC or ad hoc tribunal founding documents, the tribunals have held that this is an internationally recognized human right that must be respected. The right to privacy is not absolute and the investigative act violating it may be justified, according to the European Convention on Human Rights (ECHR), if it (1) has a legitimate aim, (2) is lawful, and (3) is proportionate to its aim.

But neither the ICC nor the ad hoc tribunals' statutes and rules address privacy rights pertaining to the collection of DNA and fingerprints from a witness or a suspect. Without consent, a warrant respecting the three conditions aforementioned is usually required to take DNA and fingerprints.

Procedure-based rules: Two procedural rules are of great importance for the collection of physical evidence: (1) the requirement for a chain of custody and (2) the special measures taken when there is a 'unique investigative opportunity' under Article 56 of the ICC Statute.

Neither the ICC nor ad hoc tribunals mention chain of custody in their Statutes or Rules of Procedure and Evidence

(RPE). The ICC prosecutor's regulations express the need for an uninterrupted and recorded chain of custody and trial chambers have mentioned the relevance of chain of custody to establish the probative value of a document or other physical material at trial. There is jurisprudence at the ICTY stating that proof of a chain of custody is not required. Article 56 of the ICC Statute, even if not entirely clear regarding its application, may be very useful when it comes to forensic evidence: the uniqueness of the investigative opportunity applies fully to physical evidence that will deteriorate or may be lost.

Admissibility of evidence

All evidence before ICTs must pass an 'admissibility test' of being relevant and having probative value, which is less strict than those of some national legal systems. It is left to the trial chambers to determine the weight of the evidence.

For instance, the ICTY's RPE provide limited guidance and adopt a flexible approach to the admissibility of evidence, strongly influenced by the philosophy of 'admit everything, determine weight later,' without a detailed set of technical rules. Evidence is admissible unless it is to the detriment of a fair trial and not otherwise excluded on the grounds stated in Rules 95 and 96 of the ICTY's RPE.

Like all evidence, forensic evidence, which is *prima facie* admissible if it is relevant to the case and probative, must be reliable and valid. Even though there is no mention of scientific standards in international courts' RPE and all the tribunals created thus far have adopted a flexible approach to the admissibility of evidence, the court, inspired by the Daubert Guidelines used in US tribunals, could consider some questions in determining the weight to be attributed to forensic evidence. Some of these criteria have been tested during examination and cross-examination, as was the case during the Radislav Krstić trial.

Forensic expert testimony within ICTs

The forensic scientists offer an interpretation of the findings in the context of the case (expert opinions) and deal with matters beyond ordinary knowledge and experience. Forensic scientists are increasingly using highly developed scientific tools, such as 3D modeling, to present their findings.

Testing the reliability and credibility of scientific evidence may involve some or all of the following related issues: (1) the expert's qualifications and status as an expert; (2) the scientific methods adopted; (3) the norms of practice; (4) acceptance within the scientific community and validation of methods through publications and peer review; (5) whether and how the science is produced for litigation; and (6) the novelty of the scientific evidence presented.

At the ICC, there is no definition of expert or expert witness and Regulation 44 states only that the Registrar has to compile and maintain a list of experts accessible at all times to all organs of the court and to all participants in proceedings, following an 'appropriate indication of expertise in the relevant field.' As of 28 June 2012, the Registry has a published list of 144 experts (individuals and organizations) from 36 different countries, their 5-year appointment being possible to be extended for a further 5 years at their request. However, experts may testify even if not registered on this list.

At the ICTY, Rule 94 does not provide an explicit definition of an expert witness, but jurisprudence states that an expert (1) 'is a person who by virtue of some specialized knowledge, skill, or training can assist the trier of fact to understand or determine an issue in dispute'; (2) 'is expected to give his or her expert opinion in full transparency of the established or assumed facts that he or she relies upon and of the methods used when applying his or her knowledge, experience, or skills to form his or her expert opinion'; (3) and may have his expertise determined by an analysis of his present and former positions, as well as by reference to his submitted curriculum vitae and publications.

At the ICTR, an expert witness is a person 'whose testimony is intended to enlighten the Judges on specific issues of a technical nature, requiring special knowledge in a specific field.'

Another challenge arises when cases involve several experts from various disciplines. In ICTY cases notably, judges accepted as evidence the testimony of a unique prosecution leading expert who had supervised and coordinated all the postmortem examinations performed by multidisciplinary and international teams of experts or had reviewed expert reports produced by international teams working independently from each others.

Problems for Forensic Science in ICTs

Evolution of Forensic Science

The 'CSI' effect

For the general public, forensic science has become a source of entertainment with many flourishing television shows. There is actually a real need for forensic scientists and international prosecutors to deal with this 'CSI effect,' that is, to manage expectations and explain the science's limitations. This is all the more important in international criminal tribunals because the fact that crime scene investigations take place well after the crime has been committed exacerbates the intrinsic limitations of forensic science.

Evolution of the use of forensic science by international courts

The early twentieth century has seen forensic evidence as secondary to eyewitness evidence. During trial held by the Nuremberg International Military Tribunal, exhibits as presumably tanned human skin samples, glass jars containing human fat soaps and bludgeons were introduced as evidence, but no forensic examination was performed.

While only few investigations were conducted on mass graves in other ad hoc tribunals, for example, ICTR or ECCC, concealed remains of victims and execution sites became a significant focus of investigation for ICTY, which supervised large-scale exhumations and autopsies involving specialists from various disciplines, including archaeologists, pathologists, anthropologists, odontologists as well as forensic photographers, radiographers, and so on. Mortuaries, operational several months per year, were set up in Balkan countries such as Kosovo, Bosnia, and Croatia. Other experts were included at a further stage for complementary examination in the field of DNA, ballistics, entomology, palynology, geology, and others.

This unique experience was not extended to the ICC and forensic investigation of mass graves and/or crime scenes remains currently exceptional. Exhumations and autopsies are considered on a case-by-case basis in order to generate focused corroborative evidence, for example, confirming a witness' testimony. Most frequently, use of forensic science concerns issues involving mobile telephones, audio tapes, digital equipment, documents, etc. Clinical examination of victims has been used in an ICC trial for bodily harm evaluation.

Evidence provided by forensic, psychiatric, and psychological examination has been introduced in some cases, for instance, with ICTY or ICTR, and recently with ECCC, mostly concerning assessment of the responsibility of the accused rather than addressing after-effects sustained by victims.

Finally, the Bayesian inference represents an appropriate interpretation tool, which can not only take into consideration more than one parameter related to scientific information associated to the recovered trace but also combine many different kinds of traces.

Forensic Expertise for Both Prosecution and Defense

In ICTs both prosecution and defense usually employ their own forensic experts to introduce scientific evidence, which ensures the equality of arms in legal proceedings. The disagreements often occur in the interpretation of the forensic scientific findings.

The defense must be able to carry out independent scientific analyses to test and verify the prosecution's scientific evidence. Sometimes, these verification and reproducibility of findings may be technically difficult. For instance, in the case of crime scene investigations involving mass graves or bombing sites, the site cannot, on a revisit, be expected to be in the same state in which it was first inspected. Nevertheless, physical evidence collected from the scene remains available for reexamination by the forensic expert for the defense who can provide reviews and counterexpertise based on the study of written reports, high-definition photographs, and/or videos, permitting a quality control mechanism of the initial expert's findings.

The prosecution expert builds the forensic action plan according to international scientific standards; he shall verify, confirm, or exclude investigation's working hypothesis while exploring all other possibilities or explanations than the one put forward by the prosecution, including any alternative theory consistent with the scientifically demonstrated facts. The defense expert seeks other possibilities or explanations than that put forward by the prosecution, providing an alternative theory with the scientifically demonstrated facts. It is the court's responsibility to decide between the different interpretations of scientific evidence and to weigh the pros and cons of all the forensic evidence presented.

Even though the experts for both the prosecution and the defense will likely possess similar experience and qualifications, many features separate them:

1. The prosecution expert is likely to have been involved in the investigation from its early stages, sometimes in permanent contact with the investigators, and may have developed his forensic action plans and strategies to support the investigation. He will almost always be the first to have

undertaken in-depth forensic examinations of all relevant exhibits. Instead, the defense expert may have no involvement with the case until much of the initial work has been completed by the prosecution.

2. The prosecution expert has very often carried out complex, and sometimes lengthy, forensic examinations. Instead, the defense expert will often need to work from information and results provided by the prosecution expert and is not likely to be in a position to see the items in their original state if forensic analyses have been carried out. His role is to assess the way in which the initial examination was carried out and its results. Sometimes, albeit rarely, the defense expert can take the initiative and produce scientific examinations of items that have not been looked at by the prosecution.

The Issues Related to Forensic Evidence with Self-Represented Accused

The international criminal tribunals have adopted various positions to the problem of the self-representation of an accused.

At the ICTY, successive accused have been allowed to represent themselves to the detriment of the efficient conduct of proceedings and possibly contrary to the ability of the court to ensure a fair trial: S. Milošević, Šešelj, Stanković, Krajišnik, Karadžić. At the SCSL, the court has recognized a 'qualified right to self-representation.' At the STL and as stated by its former President, Rule 59 of the STL's RPE deals with a number of problems that have emerged with self-represented accused from the ICTY by stating:

A suspect or an accused electing to conduct his own defense shall so notify, in writing, the Pre-Trial Judge or a Chamber of his election. The Pre-Trial Judge or a Chamber may impose counsel present or otherwise assist the accused in accordance with international criminal law and international human rights where this is deemed necessary in the interests of justice and to ensure a fair and expeditious trial.

As expressed by Cassese, the "complexity of international criminal proceedings is such that it is almost inconceivable that an accused, in order to fully ensure his defense, will not need the assistance of experienced defense counsel."

The problem of self-representation with forensic evidence is that processing hundreds of thousands of pages of material disclosed by the prosecution, including highly specialized forensic reports, is not a task that a self-represented accused can easily undertake by himself.

The capacity of courts to deliver fair and expeditious trials may inevitably require that a self-represented accused be assisted by forensic scientists even if he is not represented by professional defense counsel.

International Cooperation and Financial Implications

In days of budget constraints and even though the general belief is that forensic science is beneficial for international criminal tribunals, these courts need to make sure that the forensic examinations are worthwhile and absolutely necessary. This is one more reason why international courts and

ad hoc tribunals need to have their own forensic science capacities.

In addition, international criminal tribunals have neither the human nor the financial resources to be able to carry out in-house each kind of forensic examination, given the large spectrum of specific fields, the cost of scientific analysis, and the relatively limited budget. There is a real necessity for international tribunals to either have a list of individual experts chosen for their competence or cooperation channels with countries or international organizations to use their forensic services. For instance, the STL and the ICC have signed Cooperation Agreements with Interpol and a Memorandum of Understanding with the Dutch Ministry of Justice for the provision of forensic services by the Netherlands Forensic Institute (NFI).

Finally, although ICTs have investigative powers, they lack the power to issue subpoenas to states for evidence in their possession. Despite the fact that, in most cases, states are under obligation to cooperate, ICTs may issue only noncoercive binding orders to states. For instance, if states do not comply, the ICC can only make a finding of noncompliance and a coercive measure, if any, may only be taken by the Security Council or the Assembly of States Parties.

The Future of Forensic Science Within ICTs

Use and Understanding of Forensic Science by International Criminal Tribunals

The scientific value of forensic science for international criminal tribunals

In the last few decades, forensic science has been largely influenced by the practical needs of the international courts. The forensic evidence, for instance, first collected through investigations of mass graves and then used in court under various forms such as reports on the exhumations, autopsies, and laboratory analysis, photographic evidence, material artifacts, and expert witness testimony, have facilitated successful prosecutions in a number of trials, specifically those relating to the crimes in Srebrenica. Indeed, about 7500 men and boys were massacred in 1995 in Srebrenica, and even though the ICTY had limited resources and was concerned only with general classification of the remains, the ICTY forensic team carried out crime scene investigations in 1996 and exhumed and autopsied 517 remains. Moreover, the added value of forensic science has been highlighted in several ICTY judgments, notably in Dordevic case.

To get the best from forensic science, there is a real need for published, validated, peer-reviewed, experimentally controlled research as the basis for operating procedures and interpretational rules for practical applications.

International criminal tribunals need a better understanding of inference processes

ICTs may be increasingly confronted with statistical evidence, notably Bayesian statistical approaches, which have become popular in DNA and many other branches of forensic science in recent years.

On the one hand, forensic scientists may need to explain applicable principles and uncertainties to a bench of

nonscientists in court, where they may be subject to rigorous cross-examination.

On the other hand, it appears that probability and statistics are not always handled confidently and competently, by lawyers, judges, or even by forensic scientists. In international proceedings, a model for Case Assessment and Interpretation (CAI), based on that developed in domestic jurisdictions, could be developed and agreed upon.

Need for Permanent Forensic Structures

The international community needs a permanent International Response Team

As stated earlier, appropriate crime scene investigations are absolutely crucial for international courts. International investigation commissions often ‘reinvent the wheel,’ thereby wasting precious time and financial resources, and there is no mechanism for sharing knowledge and experience. There is a real need for coordination and definition of a uniform approach to international investigations.

The solution could be to set up a permanent UN International Response Team (IRT), which will be able to deploy in a very quick time frame to investigate international crimes once being given the mandate. Composed of lawyers, investigators, analysts, and forensic experts, this IRT would be able to gather evidence in a timely manner with all the legal, logistical, and financial tools necessary to guarantee high international standards. Sharing of resources would allow procurement of costly equipment, for example, portable x-ray machines and portable or deployable mortuaries, made available for UN agencies (for instance Department of Peace-Keeping Operations, Department of Political Affairs, and Office of the High Commissioner for Human Rights) and International Commissions of Inquiry.

Also directed to this end, the Justice Rapid Response (JRR) is an intergovernmental multilateral facility of active duty criminal justice and related professionals. These experts can be deployed rapidly at the request of the international community to investigate, analyze, and report on situations where human rights and international criminal violations have been reported. It currently has 65 participating States as well as several organizations. Since becoming operational in October 2009, JRR has successfully deployed in several instances.

International criminal tribunals need their own forensic team

In the past years, there has been an increasing recognition of the importance of crime scene investigations and forensic science within ICTs. The need for identification, collection, packaging, and transport of material with potential evidential value must be ensured in house by these tribunals, by forensic experts with extensive training in all aspects of crime scene investigations to ensure the integrity of items received for analysis by an independent laboratory.

As the ICTY's First President has mentioned, an international tribunal without its own police force, “is very much like a giant without arms and legs – it needs artificial limbs to walk . . . And these artificial limbs are state authorities. If the cooperation of states is not forthcoming, [the Tribunal] cannot fulfil [its] functions.” This statement is also very true if an international tribunal does not have its own forensic unit.

As, by definition, international courts deal with the most serious crimes, and as the great progress in analytical techniques and the electronic revolution has impacted the level of specialization of crime scene investigators, an ideal crime scene investigation would include a multidisciplinary team under the supervision of a forensic coordinator who has a thorough knowledge of the most advanced forensic procedures and is familiar with the skills of all the forensic disciplines involved.

Specific requirements for the forensic expert

The forensic scientist must primarily be skilled in applying scientific techniques to the analysis of all the different types of evidence recovered during a criminal investigation; he must also be aware of the constraints imposed by the judicial system, and the procedures and techniques used must satisfy the criteria of admissibility established by the court. A forensic expert at the international level must be trained to understand international rules.

But in an international court, the forensic scientist needs excellent communication with the investigation and prosecution divisions in order to be part of the decision-making process, because investigators and prosecutors can have only a limited view of the possibilities of forensic science to explore opportunities and because there is a risk of misinterpretation and misuse of expert opinion.

International Criminal Tribunals Need Universal Rules

Universal rules of procedure and evidence

As discussed earlier, the way in which international prosecutors can collect physical evidence and international courts can use forensic evidence is described in rules scattered across multiple sources, such as manuals, treatises, conventions, courts statutes, rules, and judicial decisions, but there is no single document incorporating all this data. This confusing situation is prejudicial, not only for the prosecution, but also for the defense's ability to ensure a fair trial.

As a consequence, there is a real need to build universal RPE applied to the forensic evidence, which must take into account the wide spectrum of international crimes. A terrorist attack such as the one investigated by the STL is quite different from the crimes against humanity investigated by the ICTY or the ICC. Nevertheless, the task should not be insurmountable because the basics of forensic science are the applications of science, which is by nature universal.

Universal rules for expert testimony

International courts may have to establish standards for expert testimony that include reliability and relevance, and may establish judges as gatekeepers.

International courts would have to develop a system to educate all those involved in their proceedings, yet assuring the neutrality of experts. One possible solution could be specific assistance provided by experts carefully selected to educate the judges, help them to decide on the admissibility of scientific evidence, critique the testimony of the parties' experts, and, where necessary, testify in trials.

The value of forensic science to international criminal tribunals is unquestionable but its use needs to mature in a systematic way in the coming years in order to consolidate its

crucial evidentiary role. Courts should be enabled to make the best use possible and ensure better understanding of forensic science and the inference processes for forensic evidence. In this context, they could also set up permanent forensic structures, such as a permanent International Response Team, and universal rules of procedure and forensic evidence as well as expert testimony within international criminal tribunals.

Introduction

Forensic professionals have attempted to form international associations almost since the first crime laboratories were established. Dr. Edmond Locard, who is credited with the first recognized crime laboratory in Lyon, France in 1910, established L'Académie Internationale de Criministique in 1929. This association of professionals which was based in Lausanne, France, did not survive World War II.

There are a number of national and regional/continental forensic professional associations which were established in the mid to late 1900s. Many of these associations of professionals are educational in nature and dedicated to promoting research and elevating scientific professionalism. Founded in 1948, the American Academy of Forensic Sciences (AAFS) headquartered in Colorado Springs, CO, USA, is among the oldest forensic professional societies. AAFS represents a wide range of forensic disciplines and promotes education through its annual technical meetings and scientific journal. In 1957, the International Association of Forensic Sciences (IAFS) hosted its inaugural meeting to help forensic practitioners exchange technical information.

Unique regional/continental networks have been established among laboratory directors of operational forensic laboratories and institutes. The American Society of Crime Laboratory Directors (ASCLD) was formally established in 1976, as a professional society dedicated to providing excellence in forensic science through leadership and innovation. In 2010, ASCLD expanded its membership to include laboratory managers and supervisors as well as laboratory directors. As a

result, its membership includes over 600 individuals from North America as well as other countries.

The network of Senior Managers of Australian and New Zealand Forensic Laboratories (SMANZFL) was established in 1986 when a group of forensic science laboratory directors met in Adelaide, Australia. The aim of the group representing (ten jurisdictions) was to establish a vehicle to facilitate regular communication among the directors of all of the major forensic science service providers within government including police. SMANZFL's principal objective was and is to promote leadership in the forensic sciences in the pursuit of excellence.

In 1992, the directors of Western European governmental forensic laboratories agreed that they should hold regular meetings to discuss topics of mutual interest. The European Network of Forensic Science Institutes (ENFSI) was established with the purpose of sharing knowledge, exchanging experiences, and coming to mutual agreements in the field of forensic science. ENFSI now has 59 members from 34 countries in Europe.

The Academia Iberoamericana de Criminalística Y Estudios Forenses (AICEF) was formed in 2004 and serves Spanish and Portuguese speaking countries in Europe and Latin America. AICEF has 32 active members from 19 different countries. AICEF is focused on the professionalization of forensic science through teaching and research and on quality systems, particularly at the crime scene.

The Asian Forensic Sciences Network (AFSN) was established in 2008. It now has 18 member institutes from 11 countries and serves as a collective representation for the forensic science community in Asia. AFSN acts as the forum for forensic science institutes in Asia for discussion on issues

relating to forensic services and is focusing its efforts on enhancing the quality of forensic services in Asia.

The *basis* for a South Africa Regional Forensic Science (SARFS) Network, representing 12 countries in Southern Africa, was established with United Nations Office on Drugs and Crime (UNODC) guidance and support in December 2008. It has since been established and is poised to join the International Forensic Strategic Alliance (IFSA) network. This network is focused on the need to join efforts and resources to advance forensic services in the region.

Having similar roles, functions, and objectives, the networks representing forensic science laboratory management ultimately realized the value to be gained through long-term collaboration and cooperation on strategic issues. As a result, in the first decade of the new millennium, a global forensic network of networks, the IFSA, was established. IFSA has no legal status but represents a cooperative entity comprising the member networks. Its vision is to create opportunities for strategic collaboration across the global forensic science community. Goals and objectives have been established for IFSA. These are:

- To represent the operational forensic science community
- To develop and execute a rolling agenda for strategic issues related to forensic science
- To be a strategic partner to other relevant international organizations and partnerships
- To encourage the exchange of information related to experience, knowledge, and skills between the member networks

A History Lesson – The Road to IFSA

“History repeats itself. That’s one of the things wrong with history” (Clarence Darrow).

IFSA was the culmination of many years effort. International meetings among individual laboratory directors began informally at the annual FBI ASCLD Symposium, the Interpol International Forensic Science Symposium and other technical meetings.

Beginning in 1996, ASCLD, ENFSI, and SMANZFL attempted to establish an informal collaboration. That year, two unofficial meetings among representatives of these organizations were held: first at the IAFS meeting in Tokyo, Japan, and again at the ASCLD meeting in Quantico, VA, USA. At the Quantico meeting, facilitated by ASCLD International Liaison Clifford Vander Ark, the three organizations agreed to meet in London at the invitation of Janet Thompson (ENFSI).

In May 1997, the three networks, now collectively called AES, met in London, hosted by the United Kingdom’s Forensic Science Service. This meeting was referred to as the International Summit. Participants generated a strategic plan for continued collaboration. The plan included three overall strategic aims for successful cooperation:

- Establishing trust, confidence, and credibility in forensic science
- Interaction to push frontiers of forensic science forward most notably by the exchange of information

- Common understanding of critical issues and how they can be taken forward

Within the context of these strategic aims, nine key topics were identified for cooperation:

- Liaison and cooperation among AES members and between AES and other organizations
- Competency assessment
- Laboratory accreditation
- Credibility/political advocacy role
- Education and training
- IAFS and the role of AES
- Organizational standards of conduct and values/personal ethics
- Performance indicators, including benchmarking
- Harnessing consumer strength

In October 1998, AES met in Lyon, France, at Interpol’s International Forensic Science Symposium. Although no progress on the strategic plan generated at the 1997 London meeting was reported, common issues were again identified and discussed among the three networks. The strategic plan was updated. An unsuccessful attempt was made to formalize AES with a Memorandum of Understanding (MOU). The MOU offered a proposed organizational structure for international summit meetings, naming a chairman and delineating responsibilities.

In 1999, although AES met in Los Angeles, CA, USA, no formal record of the meeting was made. In 2000, a meeting of AES failed to occur.

In 2001, an AES meeting at Interpol’s triennial forensic science symposium in Lyon, France, was organized by Serge Caillet, the ENFSI Chairman for fear the process ‘would have been interrupted forever.’ Again, no progress was reported on the strategic plan, but the participants renewed their interest in the AES International Summit. They determined that the goal of this meeting was to formulate an AES vision. A strategy was articulated:

- International liaisons for each participating network were deemed essential to provide continuity
- A website was envisioned to facilitate communication
- Critical issues needed to be identified for inclusion in a new strategic plan

Additionally, the participants acknowledged that there was a real need to formalize the meetings to ensure further progress of the collaboration.

In 2002, the annual ASCLD symposium was held in St. Petersburg, Florida, USA. In attendance were the ENFSI Chairman and the ENFSI Chairman Designate as well as the SMANZFL past Chairman. An informal meeting with these individuals was hosted by ASCLD President Susan Narveson. Once again, the participants agreed that international collaborations were a good idea, but no progress had been made since the previous meeting. The discussion focused on how to become more organized. It was agreed that there needed to be a strategic focus to the meetings. Each organization discussed its key objectives and it was clear that there was overlap. The group of AES representatives agreed to pursue the topics

identified in the May 1997, AES meeting. A communications strategy was deemed the top priority.

During 2003, ENFSI began major restructuring and was unable to devote major resources to the AES collaboration. ASCLD and SMANZFL, however, decided to move forward on a bilateral collaboration with an open invitation to ENFSI to join. ASCLD President Susan Johns and SMANZFL Chairman Tony Raymond began communicating via teleconferences. A meeting between ASCLD and SMANZFL/NIFS was held at the International DNA Users Conference hosted by Interpol in Lyon, France. An ENFSI representative attended as an observer. At that meeting, a bilateral agreement between ASCLD and SMANZFL/*NIFS Union, tentatively named the ASCLD SMANZFL/NIFS Strategic Alliance (TASSA), was drafted. (*The National Institute of Forensic Science (NIFS) had taken the role of enabler and SMANZFL support partner in this bilateral relationship.)

The vision for this entity was to create opportunities for strategic collaboration across the global forensic science community. The goals and objectives included:

- To identify potential improvements to the effective business management of the participating organizations
- To research and implement programs and products offered by the participating organizations
- To provide information directly to members of the participating organizations

A letter of agreement outlined an agreement to share jointly developed training, learning, and quality enhancing products in the following areas:

- Knowledge
- Assessment tools
- Research
- Operational support strategies

The agreement provided for the exchange of newsletter articles, website postings, links, and Board minutes. The organizations also agreed to communicate at least three times each year, twice by teleconference, and once through an annual visit. All meetings were to have formal agendas.

In March 2004, ASCLD, SMANZFL, and NIFS met in Wellington, New Zealand. This meeting was held to address the challenges facing a global partnership. These challenges included a lack of clear vision for the collaboration, difficulties in establishing long-term communications mechanisms, the lack of identifiable outcomes for the collaboration, and the costs associated with meeting. In June 2004, the liaisons from ASCLD and SMANZFL met in Lyon, France, to finalize details of a Letter of Understanding (LOU) to formalize the relationship and lay the groundwork for expanding collaborations to include other forensic networks. An LOU, creating the IFSA, was signed in November 2004, by ASCLD and SMANZFL/NIFS at the annual ASCLD symposium in San Diego, CA, USA.

In August 2005, IFSA met at the IAFS meeting in Hong Kong, China. During that meeting, which was attended by a representative of ENFSI, it was agreed to expand the bilateral agreement to a trilateral agreement to include ENFSI as well as ASCLD and SMANZFL and for the Agreement to include operational forensic networks only. Plans for expanded communications strategies were developed, to include those for a website. In October 2006, IFSA met in San Francisco, CA, USA. A new letter of agreement was drafted to include ASCLD, SMANZFL, ENFSI, and AICEF. ENFSI agreed to host the IFSA website. Communications/information, quality, crime scene, training, and international development were identified as priority topics for further collaborations. In 2007, at the Interpol International Forensic Science Symposium, a new LOU was signed expanding IFSA to four networks. IFSA was expanded again at the International Forensic Science Symposium hosted by Interpol in Lyon, France, in 2010, when the ASFN joined the other networks (Figure 1).

Challenges for Success

“A definition of insanity is doing the same thing over and over and expecting different results” (Benjamin Franklin).

The formation of a global network of forensic science laboratories and institutes has been slow paced. In 1994, SMANZFL proposed to ‘twin’ with ASCLD. It was not until

Figure 1 October 2010 Signing of IFSA Letter of Understanding in Lyon, France IFSA signatories seated (left to right): Paul Chui (AFSN), Greg Matheson (ASCLD), Jacobo Orellana Suarez (AICEF), Alastair Ross (SMANZFL), and Jan De Kinder (ENFSI). International Liaison Officers standing (left to right): Heesun Chung (AFSN), Susan Hart Johns (ASCLD), Tony Raymond (SMANZFL), and Peter de Bruyn (ENFSI).

2004, however, that the LOU to formalize an alliance between the two organizations was actually signed.

The forensic networks had to deal with a number of issues to ensure the success of a global collaboration. If IFSA was to succeed, it was necessary to review the history of previous attempts to establish an international network. Several observations were obvious:

- International collaborations are complex
- Each meeting of network representatives held promise but often failed to fulfill that promise
- It was difficult to sustain progress
- It was difficult to justify the costs associated with global meetings without measurable deliverables

Based on these observations, several critical underlying causes for failing to progress were identified. One of the first issues identified was the lack of organizational memory. Each participating network was represented by a president or chairman, selected or elected for a finite term, usually 1 or 2 years. Participant turnover in face-to-face meetings was close to 100%. Previous attempts at organizing AES meetings suffered because few, if any, participants had ever attended or participated in any previous meetings. There was no one who was available who could provide continuity. To compound the issue, the participating networks often lacked a consistent point of contact for their organization. This fact made communication difficult at best and nearly impossible when the correct individual could not be identified. Although some networks have addressed this by establishing a permanent office and/or an executive secretary, not all networks have been able to do so. The solution for this issue was to have each IFSA participant establish an International Liaison Officer (ILO) to serve as a point of contact for a minimum of 3 years. The ILOs duties also include attending IFSA meetings, when possible, to provide continuity and administrative support.

Communication was, and remains, one of the principle road blocks to international collaborations. This issue must be addressed on an ongoing basis with multiple mechanisms. IFSA conducted a gap analysis on communication and has developed a communications plan. The elements of the plan include:

- Establishing a schedule of regular meetings for which minutes will be recorded and distributed
- Establishing and maintaining a website which will include all relevant documents as well as recorded minutes from all meetings
- Publications (e.g., an informational brochure, annual report, etc.)
- Presentations at meetings and symposia
- Formal contacts with stakeholder groups (e.g., Interpol, United Nations, etc.)

A lack of structure was also identified as contributing to AES' failure to fulfill its promise. There was no regular meeting schedule or implementation mechanism to ensure tasks were completed, particularly as even critical tasks are performed on a voluntary basis. The responsibility for organizing meetings was to be the responsibility of the chairman or president of the organization hosting the meeting. Since the chairman of the hosting organization frequently did not attend the

previous meeting, he or she was often unaware of this responsibility, resulting in ad hoc meetings without agendas or meetings that were simply not held. The solution was to establish business rules and procedures.

Progress

In addition to establishing its operational structure and procedures, IFSA has established relationships with forensic service providers and enablers to move forward to establish its objectives. Forensic service providers/enablers are governmental or nonprofit organizations actively involved in the improvement of the practice of the forensic sciences. These agencies exist to enable and provide support and services to the forensic community. IFSA recognizes the need to work collaboratively with these organizations to promote collaboration and coordination of outreach activities. In 2010, the primary partners for IFSA included INTERPOL, NIFS, and UNODC.

IFSA has established position statements to represent IFSA's position on what each network should strive to achieve. These include:

Quality

IFSA advocates that a quality management program with agreed minimum standards and goals for continuous improvement is germane to a reliable, robust forensic science operation. The program should address the three key elements that underpin the forensic sciences product; namely, the provider, the practitioner, and the process. International standards such as ISO/IEC 17025 provide confidence and assurance to the justice sector and the broader community by ensuring and continuously raising standards and standardization across Member networks.

Ethics and Objectivity

IFSA believes the practice of forensic science must be built on a foundation of ethics, objectivity, and impartiality. Directors of forensic laboratories must avoid any activity, interest, influence, or association that interferes or appears to interfere with their staffs' independent ability to exercise professional judgment either at a technical or a policy level.

Support and Cooperation

IFSA recognizes the importance of international cooperation and collaboration between existing and emerging regional networks, their members, and forensic enablers through the free exchange, and transfer of information, knowledge, and technology that enhance regional experience, knowledge, and skills.

Education, Training, and Innovation

IFSA believes that forensic practitioners must have a strong grounding in science to ensure appropriate technical competency. Laboratories have a responsibility to build on that education with targeted ongoing training. They are also encouraged to engage with the academic community to enhance and accelerate

the forensic body of knowledge through informed innovation which should be shared with member networks.

Leadership

IFSA promotes the creation and support of an advisory infrastructure which includes current and emerging networks aimed at encouraging scientific and managerial excellence in the global forensic community. The IFSA infrastructure comprises forensic sciences network laboratory directors who understand the emerging critical issues and the implication of new technologies that have universal relevance and require robust member communication, cooperation, and/or advocacy.

United Nations Office on Drugs and Crime

The UNODC has been increasingly involved with IFSA network activities. Their Charter has been significantly expanded and was significantly enhanced when, on the 19th May 2010, the Commission on Crime Prevention and Criminal Justice, under the auspices of the UNODC, passed a resolution (Resolution 19/5) with respect to international cooperation in the forensic field.

The resolution called for international cooperation in the forensic field through:

- The encouragement and support for forensic science institutions to actively participate in regional networks as a means of developing sustainable forensic services worldwide
- The exploration of innovative ways to ensure a more effective exchange of forensic expertise and information worldwide
- The promotion of development and modernization, including education and training

The resolution also requested the UNODC to continue to support international cooperation in the forensic field and to promote and facilitate the establishment and/or sustainability of regional forensic science associations or networks. It follows therefore, that there is a strong symbiotic relationship between the UNODC networks and those of IFSA that should support the design and implementation of programs to advance the forensic sciences on an international basis – particularly, in the emerging nations.

The UNODC priorities may be succinctly stated as:

- Crime scene investigation which is fundamental to the success (or otherwise) of the role that forensic science can play in an investigation
- Drug trafficking (given its relationship to organized crime)
- Identity crime which represents an escalating risk to individuals, corporations, law enforcement, governments, and the global economy

Twinning

A possible outcome to the joint UNODC/IFSA project to survey the current provision of forensic technical assistance activities by network members as part of forensic capacity building, should be a number of 'Twinning' opportunities. Twinning is a

mechanism by which Forensic Science Networks, established forensic science facilities and/or 'enabling' organizations (e.g., UNODC, NIJ, and NIFS) can assist in the advancement of forensic science. Twinning arrangements may be network to network, network to laboratory, or laboratory to laboratory with enablers playing a strategic and/or facilitation role. The purpose of the twinning arrangement may be the provision of information, proficiency tests, training, research outcomes, or mentorship. An important part of twinning is 'matching' the organizations involved so that their respective strengths and needs are complementary. Also, critical to a twinning program are structured partnering arrangements that could lead to material assistance where this is required.

The International Forensic Summit

There have been additional attempts to establish global forensic networks. Through an initiative of the IAFS President SC Leung at the 17th IAFS Symposium held in Hong Kong, China, in August 2005, The International Forensic Summit (TIFS) was included in the IAFS program. The TIFS session was organized by an initial organization committee which included SC Leung, Susan Johns (ASCLD), and Tony Raymond (NIFS) and was designed to create a perpetual IAFS plenary session focused on global issues. The initiative brought together the representatives of forensic constituencies from the major continental plates to discuss establishing a coordination mechanism and strategy to enhance cooperation and share information. The discussions in Hong Kong were organized into three sessions: forensic issues around the world, positioning for a quality future, and future international partnerships and collaborations.

At the conclusion of the Hong Kong meeting, the initial organizing committee was expanded to include a representative of the medical community, James Young (AAFS), and a representative of ENFSI. This group formed the core of a steering committee which looked to expand the TIFS role beyond the IAFS meetings. It was proposed that TIFS be established as an annual forum to bring together a comprehensive range of forensic disciplines to include science and medicine to ensure that the profession of forensic science was coordinated on a global scale by building and promoting global partnerships among participating organizations; and by identifying and promoting strategic forensic issues. The proposed TIFS goals included:

- Providing a framework for international discussions by organizing and hosting annual working group discussion among forensic science networks
- Identifying forensic issues and potential improvements for collaborative studies and discussions
- Providing a framework to further enable the development of the forensic sciences in resource poor contexts

Several exploratory workshops were held to determine the feasibility of establishing TIFS as an umbrella organization to coordinate major forensic constituencies (forensic operations, learned societies, forensic science education, and legal medicine). These meetings included: a workshop at the EAFS meeting in Helsinki, Finland, in June 2006; a workshop at the

INTERPOL International Forensic Science Symposium in Lyon, France, in 2007; and a workshop at the IAFS Conference hosted in New Orleans, LA, USA, in July 2008.

The objectives for these workshops included:

- Establishing a framework and mechanism for an international forensic alliance
- Developing the outline of a strategic plan for TIFS
- Establishing a mechanism to build a knowledge bank via a website
- Establishing an operational forensic science managers' global working group
- Defining and establishing a framework/mechanism for the participation of 'service enablers' in the international forensic alliance
- Defining and establishing a forensic science global working group that reflects the professions and the educators

The workshops highlighted several issues for TIFS. A mechanism to facilitate communication was needed. In 2006, the National Forensic Science Technology Center (NFSTC) agreed to design, set up, and support a TIFS website on a trial basis.

Legitimacy was also a key issue during the discussions. As proposed, TIFS members would be organizations (as opposed to individuals) representing identified constituencies. Unfortunately, this issue was never fully resolved for TIFS. In some instances, the organizations were unable to support the costs associated with international TIFS meetings. In other cases, there were simply no organizations which broadly represented the key constituents.

Although TIFS sessions have been organized at IAFS conferences (New Orleans, LA, USA, in 2010; and Madeira, Portugal in 2010), the vision for TIFS beyond the plenary sessions has not been realized. Stephen Cordner, the Director of the Victorian Institute of Forensic Medicine, Australia, is the current TIFS chairman, is focused on the issues related to forensic medicine and hopes to have TIFS provide a framework that enables the development of the forensic sciences in resource poor contexts.

Business Networks

In addition to the formation of the collaborative networks at national and international level, there are a number of cross-jurisdictional-shared projects and initiatives aimed at benchmarking effective and efficient practices for forensic laboratories.

Project QUADRUPOL

The 'DEVELOPMENT OF A BENCHMARKING MODEL FOR FORENSIC LABORATORIES' involving four European Union Laboratories set the initial benchmark. (QUADRUPOL – DEVELOPMENT OF A BENCHMARKING MODEL FOR FORENSIC LABORATORIES. Project report: 31 March 2003. The project was financially supported by the OISIN II programme of the Commission of the European Union: Contract no. 2001/OIS/066.) This 2002/2003 ENFSI study conducted an in-depth analysis of four forensic laboratories in the European Union, namely Sweden, the Netherlands, Poland, and Finland.

Project QUADRUPOL aimed at a performance analysis of four participating laboratories. This analysis covered laboratory activities on casework, that is, investigations performed in connection with individual investigations of crime, but also secondary support activities of the laboratories such as: research and development, education and training, various support services, crime-scene investigations, participation in international cooperation, quality-assurance activities etc.

In essence, Project QUADRUPOL asked forensic managers:

- Are we doing the right things?
- What are our performance indicators?
- How can we compare our labs in an objective way?
- Are we cost effective?
- Can we 'recognize' different types of laboratories?

This benchmarking analysis of any differences is seen as providing a platform for the continuous production of comparison data enabling strategic business decisions for improvements in the field. Not surprisingly, the biggest challenge was to harmonize definitions across the laboratories (including fiscal, HR, and efficiency data). Consequently, a few sets of relatively simple metrics were used to make regular monitoring possible whilst limiting additional 'Project' workload.

The International Forensic Business and Economics Colloquium

This Colloquium sponsored through the West Virginia University Forensic Science Initiative and its cooperative agreement with the National Institute of Justice in 2006 pondered the following issues:

- How forensic laboratories conduct their business (given the public's awareness about the profession)
- How forensic science managers will meet challenges of resources, financials, processes, and management where the outcomes involve accuracy, quality, timeliness, public trust, and funding
- Given analysis of how forensic businesses operate, what can be done to enhance them with proven business practices

The Colloquium vision was to define the terms and lay the groundwork for current and future business and economic research in forensic science. Attendees included experts in forensic science, laboratory management, government, and academia from Australia, Europe, and North America.

The Colloquium determined that a similar study to that of Project QUADRUPOL would benefit North American forensic laboratories which, in turn, led to the Foresight Project which has involved 12 laboratories or laboratory systems (thus far) in North America. The principal driver was the fact that managers of forensic science laboratories may be good scientists, but invariably see themselves as scientists first and managers second; also, very few have management or project training and few tools to give them insights into their business processes and how they compare nationally and internationally. A need to transition the tools of business to the forensic laboratory environment was seen as a priority. Benchmarking is well known as a tool that can assist and improve performance by recognizing, understanding, and integrating better practices and models from outside the organization.

FORESIGHT is a business-guided self-evaluation of volunteer forensic science laboratories across North America. The participating laboratories represent local, regional, state, and national agencies. The process involved standardizing definitions for metrics to evaluate work processes, linking financial information to work tasks, and functions. This allows laboratory managers to benchmark performance, to assess resource allocations, efficiencies, and services value and to preserve what works and change what does not. This applies to laboratories' resources, communicating achievements, and needs up and down the hierarchy, supporting and justifying decisions, and laying the groundwork for improvement processes.

Once the metrics were agreed, the results provided laboratories in the lower quartile with upper quartile 'better practice' contact to discuss what processes may have led to that performance. The FORESIGHT Project stresses that the metrics themselves are not the answers, but are pointers or flags to the processes that are the answers to questions of improved performance and return on investment.

Obstacles to Cooperation – The Gill Report

ENFSI, like the other networks, was sensitive to the need for forensic service cooperation but the close proximity of not only multiple jurisdictions, but multiple nations under a single European Union banner made international cooperation even more pressing. ENFSI commissioned the Gill Report which was financed by the European Commission and published in December 2008. This Report published by Dr. Richard Gill of the Forensic Science Service, United Kingdom and his European Team was entitled 'Study on Obstacles to Cooperation and Information-sharing among Forensic Science Laboratories and other Relevant Bodies of Different Member States and between these and Counterparts in Third Countries.' (Study on Obstacles to Cooperation and Information-sharing among Forensic Science Laboratories and other Relevant Bodies of Different Member States and between these and Counterparts in Third Countries. Project Report: December 2008. The Report was financed by the European Commission DG Justice, Freedom and Security. Contract No: JLS/D1/2007/025.)

Dr. Gill et al. highlighted the ever increasing role that forensic science was playing in both the investigation and prosecution of crime (including global organized crime) and in the rising tide of global terrorism as military and customs/immigration authorities are increasingly turning to forensic science and technology to assist with their missions. Dr. Gill's Team helped identify not only the gaps and impediments but the current wide diversity of national and international cooperation and the role quality systems and standards play in any

cooperative venture. The Report is aimed at providing clarity and insight into the impediments that limit the sharing of information, intelligence, and databases between jurisdictions/nations and to recommend ways that these may be overcome and/or minimized.

The Report makes 36 recommendations that focus on:

- Effective communication and engagement (both face-to-face and electronic)
- Effective (mutual) preparedness
- Standardization and harmonization of quality systems/standards to facilitate effective exchange
- The strengthening of engagement between forensic community and the legal community: the police and civil and military authorities
- Reviewing forensic databases and their usefulness
- Raising awareness of legal barriers and reducing red-tape regulations
- Sharing best practice protocols from incident to laboratory
- Investigating tools to improve language barriers
- Further testing the forensic cooperation model through international consultation with other regional networks, for example, ASCLD, SMANZFL, and AICEF

Principles for the Organization of Forensic Support

J Robertson, University of Canberra, Canberra, ACT, Australia

© 2013 Elsevier Ltd. All rights reserved.

Scope of Forensic Support

The word 'forensic' can include anything which could end up in a civil or criminal tribunal or court. Hence, the potential scope of forensic support is enormous. Forensic support can be provided at the level of the individual all the way up to a very large organization. Organizations may exist in the private or the government sector. They may have forensic science as their primary business or forensic work may only be a minor part of the activities of a particular organization.

For the purposes of this article, the scope will focus on the organization of forensic support to include field-based and laboratory-based applications of science, medicine, or technology for a forensic end purpose.

An Ideal Organizational model?

At an international level, forensic support will usually include at least some of the 'field' forensic support being provided by a policing or law enforcement body or agency. 'Field' forensic support will always include crime scene examination but typically some (or all) aspects of fingerprint examination (and often fingerprint identification), firearms and ballistics, and photography or imaging will be included.

In some countries, forensic medicine and pathology support may also be a unit within a law enforcement agency.

The laboratory component of the forensic sciences may or may not be a unit within a law enforcement agency. In many instances, the laboratory will be either a stand-alone unit, or, more typically, part of a 'parent' government department. In some countries, a forensic laboratory may even be part of an academic institution.

Hence, there is no unifying or ideal organizational model for the provision of forensic support. The organization of forensic support will generally reflect how it has evolved within a particular country, influenced by historical, cultural, and political factors and sometimes simply chance and opportunity. There will be examples of carefully thought out strategic decisions in how forensic support has evolved, but it is perhaps more the norm that the evolution of a particular model has been more ad hoc.

Organizational Theory

Consideration of the principles for the organization of forensic science requires some discussion of broader organizational theory and, specifically, what may be different about the types of 'parent' organizations from which forensic support is provided.

Organizational theory includes many aspects of management and leadership and it is outside of the scope of this article to deal with these in depth.

An important focus of organizational theory in more recent times has been on change management and an increased emphasis on demonstrating accountability and effectiveness and 'doing more with less' through greater efficiency. It is widely accepted that the modern organization needs to be adaptive and capable of relatively rapid change to meet future challenges.

Academic and classical views of organizations emphasize their multidisciplinary nature with three main aspects influencing organizations. These are the social system or sociology, the personality system or psychology, and the cultural system or anthropology. The economic and political environment impacts on all organizations regardless of the 'behavioral' characteristics of the organization.

The goal of behavioral science is to understand the sometimes conflicting needs of the organization for maximum productivity, with the needs of the individual and their development. Behavioral science also attempts to provide a greater understanding of what motivates the individual. However, the individual is usually part of a larger team or work group and, as such, is influenced by that environment. Sometimes, individuals and groups are defined in terms of age groups such as the so-called baby boomers, generation X, and generation Y along with somewhat clichéd broad-brush analysis of the primary motivation for each group. As far as there is some truth in these high-level motivations, there are some implications for the leadership and management of staff and how to encourage a motivated workforce. For example, the last two decades have seen the forensic industry move from a largely male dominated occupation to a female dominated occupation, especially in the laboratory. Rapid increases in staffing levels in some aspects of forensic work have also resulted in a younger, more independent workforce with middle-aged managers.

Management can be defined as the process through which the work of individuals is coordinated and directed to achieve the goals and objectives of the organization. The role of management as an integrating activity can be summarized as shown in [Figure 1](#).

Management practices have of course changed with the passage of time from almost all organizations being hierarchical with decision making held closely by senior management, to the 'modern' organization in which knowledge and information is more widely held and shared and management is less hierarchical and is shared.

The latter has been achieved by decentralization with flatter organizational structures and increased empowerment of teams and individuals. For this approach to be successful, spans of control still need to be defined. A balanced approach would suggest that most organizations still require some level of bureaucratic structure. In particular, in government and public sector organizations, there is a need to balance an increasing need to demonstrate accountability, fair and

Figure 1 The role of management in integrating organizational performance.

uniform treatment of individuals, and the cost of the systems used to produce regularity and adherence to rules and procedures.

Forensic Organizations – A Special case?

Against this very brief background of organizational theory, the question needs to be asked as to whether or not the forensic organization has any special or unique aspects which require special consideration.

Clearly, it would be highly desirable that all organizations delivering forensic support operate in an ethical, effective, and efficient manner with a goal of meeting suitable practice standards. It is a given that such organizations must meet the highest levels of integrity and ethical behavior and many forensic practitioner groups have published specific ethical guidelines for forensic science. For many forensic providers, this is measured to some extent by seeking to meet the relevant ISO body of standards. Providers may then seek to be tested against compliance with these standards. For testing and calibration laboratories, the relevant standard is ISO/IEC 17025.

With respect to management this standard requires the following.

Management Requirements

4.1 Organization

- 4.1.1. The laboratory or the organization of which it is part shall be an entity that can be held legally responsible.
- 4.1.2. It is the responsibility of the laboratory to carry out its testing and calibration activities in such a way as to meet the requirements of this International Standard and to satisfy the needs of the customer, the regulatory authorities, or organizations providing recognition.
- 4.1.3. The management system shall cover work carried out in the laboratory's permanent facilities, at sites away from its permanent facilities, or in associated temporary or mobile facilities.
- 4.1.4. If the laboratory is part of an organization performing activities other than testing and/or calibration, the responsibilities of key personnel in the organization that have an involvement or influence on the testing and/or calibration activities of the laboratory shall be defined in order to identify potential conflicts of interest.
- 4.1.5. The laboratory shall
 - a. have managerial and technical personnel who, irrespective of other responsibilities, have the authority and resources needed to carry out their duties including the implementation, maintenance and improvement of the management system, and to identify the occurrence of departures from the management system or from the procedures for performing tests and/or calibrations, and to initiate actions to prevent or minimize such departures;

(Continued)

(Continued)

- b. have arrangements to ensure that its management and personnel are free from any undue internal and external commercial, financial, and other pressures and influences that may adversely affect the quality of their work;
- c. have policies and procedures to ensure the protection of its customers' confidential information and proprietary rights, including procedures for protecting the electronic storage and transmission of results;
- d. have policies and procedures to avoid involvement in any activities that would diminish confidence in its competence, impartiality, judgment or operational integrity;
- e. define the organization and management structure of the laboratory, its place in any parent organization, and the relationships among quality management, technical operations, and support services;
- f. specify the responsibility, authority, and interrelationships of all personnel who manage, perform, or verify work affecting the quality of the tests and/or calibrations;
- g. provide adequate supervision of testing and calibration staff, including trainees, by persons familiar with methods and procedures, purpose of each test and/or calibration, and with the assessment of the test or calibration results;
- h. have technical management which has overall responsibility for the technical operations and the provision of the resources needed to ensure the required quality of laboratory operations;
- i. appoint a member of staff as quality manager (however named) who, irrespective of other duties and responsibilities, shall have defined responsibility and authority for ensuring that the management system related to quality is implemented and followed at all times; the quality manager shall have direct access to the highest level of management at which decisions are made of laboratory policy or resources;
- j. appoint deputies for key managerial personnel (see Note);
- k. ensure that its personnel are aware of the relevance and importance of their activities and how they contribute to the achievement of the objectives of the management system.

Note: Individuals may have more than one function and it may be impractical to appoint deputies for every function.

- 4.1.6. Top management shall ensure that appropriate communication processes are established within the laboratory and that communication takes place regarding the effectiveness or the management system.
- 4.2 Management System
 - 4.2.1. The laboratory shall establish, implement, and maintain a management system appropriate to the scope of its activities. The laboratory shall document its policies, systems, programs, procedures, and instructions to the extent necessary to assure the quality of the test and/or calibration results. The system's documentation shall be communicated to, understood by, available to, and implemented by the appropriate personnel.
 - 4.2.2. The laboratory's management system policies related to quality, including a quality policy statement, shall be defined in a quality manual (however named). The overall objectives shall be established and shall be reviewed during management review. The quality policy statement shall be issued under the authority of top management.

A key element of ISO/IEC 17025, with respect to organizational management, is an emphasis on impartiality and that staff are free from any pressures which might influence their technical judgment.

Further, the requirements are explicit in saying that where a laboratory is part of a larger organization, the organizational arrangements should be such that departments having conflicting interests must not adversely influence the laboratory's compliance (see Management Requirements).

An example of potentially conflicting interests could be the police investigators' view of what forensic support is required and the role of the forensic provider in this decision-making process.

Finally, the requirements also emphasize that managerial and technical personnel have the 'authority' and 'resources' to carry out their duties.

In addition to these general requirements, the Australian (National Association of Testing Authorities, NATA) application document has supplementary requirements (SRs) for accreditation in the field of forensic science.

These requirements again emphasize that the laboratory director's authority must be well defined, with sufficient authority commensurate with his/her responsibilities. There must be sufficient delegation of authority to managerial/supervisory staff, supervisors must be commensurate with their responsibilities, each subordinate should be accountable to only one immediate supervisor per function, and performance expectations must be established and understood by laboratory personnel.

Management must have a business plan and manage budgets to provide services to meet customer requirements and the laboratory must have and use a management information system which provides information which will assist it in accomplishing its objectives.

This document is more specific than the general ISO/IEC requirement in that it spells out in greater detail the authority and responsibilities of the laboratory director. It is also explicit in saying that there shall be a business plan and a budget suitable for the laboratory to meet its objectives.

An interesting requirement is 4.1.5.a., where it states that "the organizational structure must group the work and personnel in a manner that allows for efficiency of operation, taking into account the interrelation of various forensic disciplines."

The SRs recognize that there is no single perfect organization for a forensic laboratory.

The SRs also have quite a lot to say about the responsibilities of supervisors, channels for communication, and input from staff including human resource policies.

Hence, while there are some nuances, which may be forensic specific, the guiding principles from an organizational management perspective are largely common irrespective of the nature of the business. Forensic science providers should seek to meet the levels of service and other characteristics as described in ISO 17025.

For nonlaboratory providers, the same management principles should be met irrespective of any alternative technical standard such as ISO 17020, which has been proposed in some parts of the world as a suitable standard for crime scene operatives.

Public Versus Private Providers

As many forensic support groups are within law enforcement agencies, the issue of forensic management having appropriate authority, control of adequate budget, and management structures to demonstrate appropriate independence from undue

influence are critical to enhance public perception of the impartiality expected of forensic science. While the same observations are equally applicable regardless of parent organization, there is a greater perceived chance that forensic decisions could be subject to inappropriate influence when the parent organization is within law enforcement.

Forensic science support is largely based in the public sector. As stated earlier, this does not mean that improved and more efficient services are not expected. However, it has been argued that as a government function the need to provide a large number of activities and the exposure to political initiatives come at a real cost which affects any assessment of how private sector techniques can be applied. A private sector model for laboratory forensic support has been introduced in England and Wales and in New Zealand. In the former country, commercial pressures have led to the Forensic Science Service (FSS) being dismantled with the government aim being to have no state interest in a forensic provider. However, the state will of course retain a major interest through 'ownership' of their police services and 'in house' forensic support. In New Zealand, the model has been described as at best 'pseudo-commercial.' Under this model the provider is a Crown Research Institute (CRI) and is required to:

- undertake research,
- pursue excellence in all its activities,
- comply with applicable ethical standards,
- promote and facilitate the application of the results of research and technological developments,
- be a good employer, and
- exhibit a sense of social responsibility by having regard to the interests of the community.

As a CRI, unlike a State-Owned Enterprise (SOE), a CRI is not required to 'enhance commercial returns to government.'

It is not the purpose of this article to promote one service delivery model over another but to recognize that, regardless of the provider model, an unavoidable requirement of any organization today is to be accountable and to demonstrate it is running in a cost-efficient manner. The challenge for any

organization is how to demonstrate a balance of effectiveness (and define what this means) and efficiency (lowest acceptable trade off of unit service cost).

People Are Our Most Valuable Asset!

Are there any specific aspects relevant to the management of scientists and technicians in a forensic environment and will the change in balance of employees have implications for organizations?

In a general sense, there has been a move away from hierarchical management structures toward flatter structures and from classical team organization to an expert team or cross-functional team mode. For example, see Figures 2 and 3.

These models may suit the 'modern' employee as they devolve decision making and encourage elements of self-run teams; however, they have implications for organizations with more traditional management structures. Whichever model of team environment is used a key element to success is staff motivation. There are a number of well regarded theories of motivation including Maslow's needs model and modifications (simplifications) of this model such as Alderber's ERG theory where E stands for 'existence', R for 'relatedness', and G for 'growth'. These, and other theoretical treatments, suggest that for specialists there is a greater need for a higher degree of independence, challenging tasks, and open and honest communication, and recognition of job status.

Finally, these motivators need to be considered against an age matrix for individuals as motivation changes according to age. As forensic science requires job and life experience and knowledge acquisition, forensic scientists are likely to experience increased motivation as their abilities increase and results in enhanced self-image.

However, this may decline in older employees as they believe they enter a period of biological decline and cognitive ability. Initially, they may compensate for this by simply working longer hours.

Figure 2 Expert team organization. Adapted from Laegaard and Bindslev (2011).

Figure 3 Cross-functional team organization. Adapted from Laegaard and Bindslev (2011).

In conclusion, human resource management is complex without simple easy to follow guidelines. Forensic scientists are only 'different' in the same sense as many specialist professionals and good management practices should recognize the factors likely to motivate specialists. In so far as organizational structures can be modified a more empowering model is likely to achieve the best outcomes when managing knowledge workers.

Conclusions

From an organizational management perspective, the forensic science 'industry' is not unique but it has some individual elements which require careful consideration and management. The 'workforce' is dominated by knowledge workers or science specialists. While there is still significant disparity of the level of academic qualifications across the industry, professional development is recognized as essential. Typically, forensic science providers will be part of a larger parent organization with a different mix of staff which may present some culture issues for managers of the forensic component.

Important organizational-level issues include a focus on appropriate levels of impartiality of service and some quite specific requirements if formal accreditation is sought at ISO level.

Finally, forensic providers are not immune from broader management issues including a change in culture and

environment and the desire for greater accountability and demonstrated efficiency.

Quality Assurance

Introduction

Given that results generated by a forensic science facility may lead to the conviction or exoneration of an individual accused of a crime, may determine a cause of death, or may identify the victim of a criminal act or natural disaster (for example), systems need to be in place to ensure reliability, accuracy, and precision. It is expected that the scientific methods employed will be fit-for-purpose and will be applied in accordance with accepted international standards. Many factors impact on quality assurance (QA) in the forensic arena, from how samples are collected and transferred, how examinations and analyses are undertaken, the qualifications and training of staff, through to how results are communicated in written reports and otherwise presented in court.

QA is defined as “a program for the systematic monitoring and evaluation of the various aspects of a project, service, or facility to ensure that standards of quality are being met” (Merriam-Webster’s Online Dictionary, 2011). It is an activity designed to provide evidence to all stakeholders that activities related to the delivery of a service or the manufacture of a product are being performed effectively and to an appropriate standard. QA assures the existence and effectiveness of procedures that attempt to make sure – in advance – that expected levels of quality will be reached. Various international standards exist that can be used as the basis for establishing a QA system. Examples include the ISO 9000 family of standards and ISO 17025, which specifies the general requirements for the competence of a laboratory to carry out tests and/or calibrations. Formal accreditation of a facility by an external accreditation agency, against a relevant international standard

such as ISO 17025, provides independent verification that an appropriate QA system is in place.

The purpose of this article is to provide a general understanding of QA practices as applied to the delivery of forensic science services. As the most relevant international standard for a forensic science laboratory is arguably ISO 17025, this standard will be the focus of the information presented. The American Society of Crime Laboratory Directors Laboratory Accreditation Board (ASCLD/LAB) in the United States, the United Kingdom Accreditation Service (UKAS), and the National Association of Testing Authorities (NATA) in Australia are examples of accreditation bodies that can officially accredit forensic facilities against ISO 17025.

General Principles

To ensure the quality of reported results, each forensic laboratory should have an established QA program. These programs, when strictly maintained, are designed to ensure that such results are scientifically valid, and that opinions are based on observations and analytical data that are credible and reliable. A properly established QA program will contain a number of requirements that must be adhered to by all staff working within the facility, including laboratory management, technicians, and casework analysts. Such requirements will generally include:

- An organizational structure appropriate for the range of activities undertaken
- Required education and training of staff
- Appropriate facilities, including laboratory, office, and storage areas (with adequate security and access control)

- 'Fit-for-purpose' equipment that is regularly maintained and calibrated
- Case file and exhibit management systems
- Documented methods and procedures (to cover both administrative and technical activities)
- Regular audits, quality control (QC) tests, and staff proficiency tests for the ongoing monitoring and assessment of performance
- Routine peer review of case files, results, and reports

The QA program should also embrace a philosophy directed at continuous improvement and addressing customer needs. For a forensic science facility, the 'customer' may be seen as law enforcement, the courts, and ultimately the general community. Addressing customer requirements does not mean focusing on giving a police investigator the analytical results that they need to implicate a suspect! It means providing an objective, scientifically reliable service in a timely fashion, and ensuring that any evidence generated can withstand the most rigorous scrutiny in court.

Quality may be defined as the degree to which a service (or product) meets a defined set of requirements. In a laboratory environment, QA describes the overall measures that a laboratory uses to ensure the quality of its operations and the reliability of its reported results. QC refers to the operational techniques and activities that are used to fulfill the requirements for quality. They are the procedures undertaken by laboratory staff for the continuous monitoring of procedures and analytical results in order to determine whether these results are sufficiently reliable for release to the client. As such, QC is a key element of QA, aimed at ensuring the quality of test results reported for individual samples or sample batches.

A laboratory may decide to establish a QA program that addresses specific requirements as defined by an international standard or a relevant external accreditation body. Once the QA program is established, the laboratory may then seek formal accreditation with an external body. The term *accredit* is defined as "to recognize or vouch for as conforming with a standard" (Merriam-Webster's Online Dictionary, 2011). As such, laboratory accreditation by an external agency constitutes independent verification that the QA measures in place satisfy all of the management and technical requirements of the relevant international standard and/or requirements otherwise specified by the accreditation body. It is important to note that formal laboratory accreditation does not guarantee the quality of reported results; however, it provides a sound basis for achieving this outcome.

Essential Elements of a QA Program

While not exhaustive, the following provides an overview of the elements that are generally considered being essential in a QA program for a forensic science facility.

Personnel

Staff need to be suitably qualified and experienced for the activities they are required to perform. Appropriate training and competency testing are also required before staff are authorized to undertake casework (or related analytical

activities) unsupervised. Regular monitoring of staff performance is also required, via periodic proficiency testing or the evaluation of QC data produced by them. Records need to be kept regarding staff training, competency testing, casework authorization, and performance monitoring.

Accommodation and Facilities

Laboratory and office accommodation must be suitable in construction and size to perform the range of activities undertaken. Environmental conditions must be appropriate (e.g., temperature, humidity, lighting, dust-free, clean and sterile laboratory, etc.). Critical environmental conditions, such as the storage temperature for certain exhibits, must be monitored to ensure that they remain within acceptable limits.

The accommodation should allow for the separation of noncompatible activities (e.g., DNA extraction area separated from DNA amplification area; firearm testing facility separated from gunshot residue analysis area, etc.). Secure storage areas are required to prevent cross-contamination and deterioration of exhibits and associated subsamples.

Good housekeeping is required in the laboratory to provide a safe working environment and to ensure that samples are not contaminated prior to analysis.

Equipment and Instrumentation

All equipment and instrumentation used within the laboratory need to meet specifications that are consistent with the intended purpose, be suitably maintained to ensure satisfactory performance, and be calibrated against recognized standards (where relevant).

In-house maintenance, safety, and calibration checks need to be performed in accordance with documented procedures and at defined intervals. Records of these checks need to be maintained and monitored to detect any significant degradation in equipment performance over time.

Measurement Standards

Measurement standards are defined as chemical or physical standards that are used for calibration or validation purposes. A collection of relevant standards, with each standard certified by an external body where appropriate, needs to be retained by the laboratory. Use of these standards should be documented, and the standards themselves stored in a manner to preserve their integrity.

Standard Operating Procedures

All policies, procedures, and operating instructions that may impact on the quality of the services and the analytical results provided need to be fully documented. Standard operating procedures (SOPs) should be in sufficient detail to ensure consistent application. There needs to be a formal approval process for new or modified procedures, and staff should be aware of, and clearly understand, all SOPs relevant to their role within the laboratory. It is expected that staff will strictly adhere to these SOPs unless there are sound reasons for doing

otherwise. The justification for deviating from an approved procedure must be documented in the relevant case file.

Sampling and Sample Management

Sampling procedures must be appropriate for the intended purpose. Bulk material or large consignments (e.g., large drug seizures) need to be subsampled prior to analysis. Representative subsamples need to be taken that will depend on the likely homogeneity of the material in question. Prescribed sampling procedures need to be documented and followed.

Exhibits submitted to the forensic laboratory need to be kept secure and guarded against contamination or deterioration. Items and related subsamples need to be appropriately packaged, sealed, and labeled. The means of sample identification must ensure that traceability is maintained throughout the process from receipt, to subsampling, sample preparation, analysis, retention, and ultimate disposal (return or destruction). Clear links must exist between analytical results and the samples that they relate to. Exhibit continuity (chain of custody) must be adequately recorded so that integrity can be demonstrated in court.

Validated Methods

It must be possible to demonstrate, through validation or verification records, that all analytical methods used in the laboratory are fit-for-purpose. 'Verification' is required before a standard method is brought into service, when a new analyst uses an existing method, or when a new instrument is commissioned (for example). At the very least, the expected accuracy and precision should be demonstrated using previously tested samples or measurement standards. Full 'validation' is required if significant modifications are made to a standard procedure, or if an in-house method is developed. Such validation involves defining the specific requirements of the method and then evaluating the relevant performance characteristics to demonstrate that the requirements are fulfilled. Comprehensive records of method verification or validation need to be retained.

Reagents and Standards Solutions

The quality of all reagents (including prepared solutions) should be appropriate for the prescribed purpose. Important properties may include reagent purity and the nature of any impurities. Prepared reagent solutions need to be clearly labeled to identify the solution components, their concentration, date of preparation, expiry date, storage requirements, safety warnings, and the name of the person who prepared the solution.

All reagents (including prepared solutions) must be stored in a manner to maintain their integrity until at least the expiry date. Critical reagents (i.e., reagents where there is a small tolerance, otherwise analytical results may be compromised) should be tested prior to being applied in casework.

Technical Records and Reporting

Each case file should contain original observations, derived data, and any other information collected or generated during

the course of the examinations or analyses performed in relation to that case. This information may include handwritten notes, work sheets, instrument printouts, photographs or digital images, and administrative paperwork (e.g., examination request forms, correspondence, relevant database printouts, etc.). Each page in the case file should be numbered, should carry a unique case file reference number assigned to that case, and should be signed and dated by the analyst responsible. Any alterations to original records need to be noted, signed, and dated.

Completed case files, and related reports, should be independently checked by a suitably qualified analyst not involved in the case in question.

All records should be legible, easily retrievable, and safely stored to prevent unauthorized access, loss, damage, or deterioration. The information contained in each case file should be sufficiently detailed to permit a comprehensive review by another individual at a later date and, if necessary, repeat analyses under the same (or very similar) conditions.

Procedures must be in place to ensure the protection and regular back-up of all computer-based information relevant to each case.

Quality Control

QC procedures need to be in place for the routine monitoring of analytical results so that the validity of such results can be demonstrated. The level and nature of the QCs required will depend on various factors including the purpose of the analysis, the technical difficulty, the frequency of testing, the required accuracy and precision, and the nature of the samples being analyzed. Effective QC programs will generally incorporate both internal and external QC measures relevant to the scope of the laboratory's activities.

Internal QC

For routine analyses, it is widely accepted that about 5% of samples analyzed (or less for robust standard methods) should be a QC sample – that is, a sample, used to check the performance of the technique, where there is an expected analytical result. Suitable internal QC procedures may include the analysis of reagent or substrate blanks, the analysis of 'spiked' samples, the analysis of previously analyzed samples, the replicate analysis of samples, and the analysis of intralaboratory 'blind' samples. A documented procedure is required that specifies the acceptance criteria for QC data and the corrective measures required if QC data fall outside the accepted range.

External QC

Interlaboratory collaborative trials or sample exchanges provide an opportunity for a facility to verify their analytical results against those reported by other laboratories for the same samples. In addition, there are external providers (see section 'Proficiency Tests') that can supply 'blind' samples of known composition for QC testing purposes.

Proficiency Tests

A proficiency test (PT) is a 'blind' test submitted to an analyst for processing. The analyst will generally be aware that the case is a PT, but they will not know the expected outcome. Samples submitted in this fashion need to be analyzed following the laboratory's standard procedures and a final report submitted to the test provider. The test provider will then determine if the expected outcome has been achieved. Any deficiencies then need to be investigated and resolved. PTs can either be internal (prepared by someone else within the laboratory) or external (purchased from an external provider or supplied by another laboratory as a collaborative exercise). A PT serves as a QC exercise for both the individual (i.e., competency of the analyst) and the laboratory (i.e., validity of test methods, equipment, reagents, etc.).

Collaborative Testing Services (CTS) is an example of an external PT provider relevant to the forensic science community.

Internal Audits

An effective audit program can make a significant contribution to overall QA. Routine internal audits involve regular inspections to check on compliance against documented procedures. Horizontal audits cover a single aspect of a laboratory's quality system – for example, exhibit handling or case file management. Vertical audits follow the progress of a case from receipt, through examination, sample analysis, interpretation of results, reporting, and case finalization. Internal audits should, over a specified period (e.g., 12 months), cover all aspects of the laboratory's QA program.

Internal auditors should, preferably, be independent of the activities being audited. They should also be suitably trained, and have qualifications and experience relevant to the audit. Issues that arise during an audit should be appropriately investigated and resolved.

External Audits

External audits, undertaken by an accreditation agency or by representatives from another laboratory, for example, provide an independent means of ensuring that the QA program is operating efficiently and effectively. Such audits can be useful for identifying weaknesses in a quality system and opportunities for improvement. Laboratories that take the view that external audits are a means for cooperatively finding ways to improve QA and laboratory performance are most likely to gain maximum benefit from such exercises.

Continuous Improvement

A high level of QC, with routine monitoring and corrections to systems and procedures as deficiencies are identified, will help achieve high standards and an environment for continuous improvement. The laboratory needs not only to effectively respond to identified problems, but also be alert to technical and procedural developments in their field (e.g., through monitoring technical journals and publications, attending relevant conferences and symposia, etc.). Staff should be encouraged to

be proactive with respect to introducing improvements into the laboratory's operations.

ISO, ISO 17025, and ISO 17020

International Organization for Standardization

The International Organization for Standardization (ISO) is an international standard-setting body composed of representatives from various national standards bodies. Founded in 1947, the organization produces worldwide industrial and commercial standards. While ISO is a nongovernmental organization, it has an ability to set standards that often become law, through either international treaties or national standards. There are currently around 160 members, each of which represents one country. ISO frequently collaborates with the International Electrotechnical Commission (IEC), which is responsible for the standardization of electrical equipment. Standards developed through a Joint Technical Committee are prefixed with ISO/IEC.

The term 'ISO' is not an acronym, but originates from the Greek word *isos*, meaning equal. ISO's main products are the International Standards, but the organization also creates other documents such as technical reports, technical specifications, publicly available specifications, and ISO guides.

As of February 2007, the ISO Central Secretariat (ISO/CS) operates from new premises in Geneva, Switzerland.

ISO 17025

ISO/IEC 17025 (generally referred to as ISO 17025) is the main standard that is relevant to laboratories that produce testing and calibration results. The first edition, released in 1999, replaced ISO/IEC Guide 25. There are many commonalities with the ISO 9000 family of standards, but ISO 17025 adds the concept of technical competence to the equation. Since its initial release, an updated version was produced in 2005 that was primarily aimed at having the terminology more closely aligned with the 2000 version of ISO 9001. For example, references to 'quality system', 'client', and 'conformance' were changed to 'management system', 'customer', and 'conformity,' respectively. Testing and calibration laboratories that comply with ISO 17025 requirements are considered to also operate in accordance with ISO 9001.

There are two main sections in ISO 17025 – Management Requirements (Section 4) and Technical Requirements (Section 5). Management requirements are primarily related to the operation and effectiveness of the quality management system within the laboratory. Technical requirements address the competence of staff, methodology, and test/calibration equipment.

Laboratories can use ISO 17025 as a basis for implementing a quality system aimed at improving their ability to consistently produce valid results. ISO 17025 is also the basis for accreditation from a recognized accreditation body (e.g., ASCLD/LAB in the United States, NATA in Australia, and UKAS in the United Kingdom). Since the standard is about competence, accreditation is simply a formal recognition of a demonstration of that competence.

The advantage of working against a common standard such as ISO 17025 is that acceptance of testing and calibration results between countries is facilitated. This is further enhanced if the laboratories in question obtain accreditation from bodies that have entered into mutual recognition agreements with equivalent bodies in other countries where the same standards are recognized. Accreditation against ISO 17025 is gaining headway around the world with respect to the delivery of forensic services. While it has not yet gained a high profile in the court systems, it is anticipated that forensic science laboratory accreditation will at some point become mandatory, with every major facility becoming accredited.

ISO 17025 describes the 'general requirements' for the competence of testing and calibration laboratories. These requirements are designed to be generic – that is, they apply to all types of testing and calibration – and therefore, they often need to be interpreted with respect to the type of calibration or testing concerned and the techniques involved. For this reason, accreditation bodies often provide 'supplementary requirements' that are specific to the particular field of accreditation (e.g., forensic science). This is the case with NATA and ASCLD/LAB-International, for example. A forensic science laboratory seeking to obtain or retain accreditation therefore needs to meet all of the general requirements in ISO 17025 as well as the specific requirements detailed in the supplementary document provided by the accreditation body.

ISO 17020

While ISO 17025 is focused on testing and calibration laboratories, ISO/IEC 17020 sets out general criteria for the operation of various types of bodies undertaking activities related to inspection. Adherence to ISO 17020 requirements is designed to ensure that 'inspection bodies' carry out competent, independent, and impartial inspections to provide their clients with information in terms of conformity with regulations, standards, or other specifications. Historically, ISO 17020 has covered inspections in relation to product design, products, material and equipment installations, plant processes, and related services. The testing performed by an inspection body may be functional or analytical. Functional testing, for example, the load testing of a crane, is within the scope of ISO 17020. Analytical testing, as performed inside a laboratory under well-controlled environmental conditions and using more sophisticated equipment or testing procedures, falls outside the scope of this standard. Therefore, inspection bodies wishing to undertake laboratory-type analytical testing as part of an inspection need to do so in accordance with the relevant requirements in ISO 17025. In general terms, ISO 17020 serves to regulate inspection facilities that have to make pass/fail decisions. ISO 17025, on the other hand, regulates testing laboratories that have to provide measurement results.

The European Network of Forensic Science Institutes (ENFSI) has been working with the European cooperation for Accreditation (EA) to formulate a consistent approach to the accreditation of the crime scene examination discipline throughout Europe. It was decided that the international quality standard for inspecting bodies, ISO 17020, was the most appropriate standard for crime scene investigation. EA and ENFSI subsequently developed guidelines to assist the

application of this standard and this has been published as 'EA-5/03 Guidance for the implementation of ISO/IEC 17020 in the field of crime scene investigation.' In contrast, bodies such as ASCLD/LAB and NATA offer accreditation of the crime scene examination discipline against ISO 17025 (not ISO 17020).

Standard Procedures

As indicated above, it is expected that a facility will perform their work in accordance with SOPs. Each procedure needs to be documented and validated (or simply 'verified' if based on a widely accepted method). In an effort to standardize the work done across a number of forensic science disciplines, various organizations internationally have developed (or are in the process of developing) recommended guidelines and standards. While not an exhaustive list, these organizations include:

- The ENFSI and their associated Expert Working Groups
- The Scientific Working Groups (SWGs) sponsored by the US FBI Laboratory, for example:
 - SWGDE – Digital Evidence
 - SWGDOC – Questioned Documents
 - SWGDRUG – Analysis of Seized Drugs
 - SWGFAST – Latent Fingerprints
 - SWGGUN – Firearms and Toolmarks
 - SWGMAT – Materials
 - SWGSTAIN – Bloodstain Pattern Analysis
- ASTM International, through Committee E30 on Forensic Sciences
- Standards Australia, in collaboration with the National Institute of Forensic Science (NIFS), through Committee CH-041 on Forensic Analysis

Conclusions

Over the past decade, there has been increasing awareness of the need for formalized QA programs for forensic science service providers. Such programs need to be based on relevant international standards, with ISO 17025 being arguably the standard that is the most applicable in the forensic science arena. QA principles should be applied to all forensic science disciplines and all aspects of service provision, including the suitability of facilities and equipment, the qualifications and training of staff, sample collection and sample continuity, the application of validated methods and QC measures, and the reporting of final results. Important elements of a QA program also include the ongoing review of activities, the systematic rectification of problems as they are encountered, and a general philosophy of continuous improvement.

A number of accreditation bodies around the world now offer specific accreditation for forensic facilities against ISO 17025. Formal accreditation provides an independent verification that an organization's quality system is fit-for-purpose and addresses all of the relevant requirements of the standard. This can assist in ensuring quality and integrity whenever scientific evidence is presented in court.

Glossary

Accreditation The process whereby an organization is formally assessed, against set standards, by an independent external body.

Certification The award for having met a set of standards awarded by an independent component body.

Competence The skills, knowledge, and understanding required to carry out a role, evidenced consistently over time through performance in the workplace.

Continual professional competence The ongoing activities to ensure continual competence to perform the role.

Continual professional development The ongoing activities for an individual to continually develop their knowledge and understanding.

Forensic Science Regulator The role created by the United Kingdom Home Office to set, maintain, and monitor quality standards in forensic science within England and Wales.

ISO standard Standard set by the International Organization for Standardization.

Registration The process of registering someone, often viewed as part of a list, as having achieved a particular standard in a specific area.

Validation Validation is the process whereby an organization, often an academic institution (College or University), judges that a program of study developed and delivered by an organization is of an appropriate quality and standard to lead to it being validated and generally leading to an award of the College or University.

Introduction

When defining forensic science, one could concisely paraphrase it as “the application of science within a legal framework.” Effective forensic science therefore demands that the ‘science’ must be carried out to a quality standard. However, the quality standard within the investigative process (scene to court) may differ from country to country, organization to organization, police force to police force, forensic laboratory to forensic laboratory, or individual to individual. However, whatever the standard, it is imperative that in each and every case, the evaluation and the interpretation in the application of the science must be acceptable to the needs of the investigation and sufficiently reliable for the courts of law. This is because it is the courts of law to which the forensic science practitioner is ultimately accountable. They may be responsible to the investigating officer for a particular enquiry but accountability is different and it needs to be incumbent on the forensic practitioner to ensure they accept this accountability to the court. Further, considering the potential consequences of poor-quality science or investigation, and the legal consequences that could include an inappropriate line of enquiry, a wrongful conviction, or the release of a suspect, it is essential that the science be carried out to a suitable quality standard to support an effective justice system.

How can the organization, police force, forensic laboratory, or individual ensure they meet the appropriate quality standard? In the article covering quality assurance, it was noted that “QA assures the existence and effectiveness of procedures that attempt to make sure – in advance – that expected levels of quality will be reached.” This is certainly one internal mechanism that the organization can use to ensure a quality standard. But crime-related activities are not unique to a specific geographic location. The contact trace is no longer seen as a local or national phenomenon but collectively within the

investigative process as viewed at an international level. A level which enables that contact trace to be recovered, examined, analyzed, and interpreted within the context of the case can and should be global. There are common acts of criminal activity such as theft, damage, fraud, sexual offenses, and murder across the globe – so why not an international quality standard for scientific investigation of crime? Under such circumstances, an appropriate quality standard developed and introduced is the ISO standard developed by the International Organization for Standardization. One such standard is the ISO/IEC 17025 (ISO/IEC 2005), which is used to demonstrate that laboratories operate a quality system, are technically competent, and are able to generate technically valid test results. In addition, it specifies the general requirements for the competence to carry out tests and/or calibrations including sampling. This ISO standard can therefore cover the organization/laboratory practices and procedures within the investigative process. The question then arises that if ISO 17025 is appropriate to laboratory examinations, can it also encapsulate the scene of crime examinations? There is an interesting debate here but suffice it to say that there is another standard ISO/IEC 17025 (ISO/IEC 2012), which applies to inspection activities, and this has been adapted for crime scene investigation in Europe. So collectively, the investigative process from scene to court can be covered by the two ISO standards 17020 and 17025. It could be argued that for the investigative process to be truly integrated and global, it necessitates one ISO or equivalent standard. This is certainly true in other parts of the world such as Australia with crime scene activities also being covered under ISO 17025.

Hence, having set the quality standards for scene to court, an organization can be formally assessed against these standards by an independent external body. This process is referred to as accreditation. There are a number of organizations covering accreditation. In the United States; they have The

American Society of Crime Laboratory Accreditation Board (ASCLD/LAB), in Australia, the National Association of Testing Authorities (NATA); and the United Kingdom has the United Kingdom Accreditation Service (UKAS). This results in organizations being accredited to the standards of ISO 17025/17020 with specific areas referred to as the scope of the accreditation.

Hence, the organization, the police force/forensic laboratory, and an individual can be accredited. In the main, these standards apply to the organizations whose main work is concerning prosecution. However, it is often argued that many of the rules applying to those working in the investigative process for the prosecution should also be applicable to those working for the defense. This would imply that those working for the defense should also be accredited to the same standards. In fact, in England and Wales, the Forensic Science Regulator (FSR) takes the view that "all forensic science analytical work, regardless of who it is conducted by, should be done to the same standards and quality assessed, where possible, through accreditation by UKAS."

It is worth noting that individuals or small companies often argue that accreditation is too costly and onerous. However, they should still have an appropriately scaled quality management system.

Defining Accreditation

Within the ISO, Guide 2 accreditation is defined as a "procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tests."

More recently, the FSR defined accreditation within its Code of Practice and conduct as "Third-party attestation related to a conformity assessment body conveying formal demonstration of its competence to carry out specific conformity assessment tasks."

Hence, to put accreditation simply, to be accredited means having all your policies, practices, and procedures documented to meet a standard and ensuring that what you do practically follows your documentation. As noted earlier, accreditation against the two key ISO standards (17020 and 17025) relevant to the investigation process is carried out by a number of authorized organizations worldwide.

Accreditation therefore enables an independent confirmation of organizational competence (having policies in place, a quality management system and audit systems to support self-regulation). This also, arguably, implies individual competence for practitioners.

Competence

One common word in the above definitions of accreditation is competence. It is this single word which seems to cause more debate than any other. The key question is, therefore, whether the ISO standards provide evidence of the competence for the organization *and* specifically the individual within the organization. They certainly do so for the organization but the accreditation should also encapsulate the competence of each and every individual involved in the creation of the

information for the courts. This is because it will be the individual who delivers the written report or statement for the investigating office and the courts of law. There is an interesting debate here in terms of accountability. If the individual is accountable to the courts and there is an issue or miscarriage of justice, does the management team of the organization carry any of the accountability as well as the individual?

Although there is an element of corporate management responsibility, it is the individual practitioner who delivers the written reports and statements and presents the oral evidence in court. So the competence of the individual is critical.

The bringing together of organizational process and individual competence within ISOs 17025 and 17020 is essential. You can have competent people working in competent organizations with incompetent processes which will result in errors and quality failure. You can also have incompetent people working with competent processes within competent organizations.

However, the question of nonaccredited independent specialist expert witnesses is also an important factor. The key here is that the 17025 standard is specifically written for laboratories and is linked to technical competence rather than competence of individuals to objectively secure, assess, and interpret data. One of the forward-thinking benefits of the 17020/25 standards is the global consistency for all forensic providers toward their justice system. This also places accountability for meeting the standards on senior managers as well as the forensic practitioner. The ISO standards do provide competence at the corporate level and while carrying out inspections do expect to see training plans, training records, and watch the demonstration of various procedures. However, it is generally not possible for the assessment team to see each and every individual at each and every visit. It is expected that the organizational policies, practices, and procedures will ensure competence of each and every individual. However, during any accreditation visit, they can check various records of the authorized analysts to ensure they have received training, professional development, and carried out any competence testing.

So within the ISO 17020 and 17025 standards, it is clear that there is organizational accreditation within policy and process and a good overview of staff competence but ongoing individual accreditation is more down to the process rather than actually continually testing the individual. So the key is not necessarily the policy and process, which are important, but the demonstration of individual competence.

Defining Competence

It is perhaps worth attempting to define competence, which will embrace continual professional development and continual professional competence as well.

The ILAC-G19-2002 section 5.2.1 defines competent as implying that staff possess the requisite knowledge, skills, and abilities to do the job. It further requires that the laboratory should also include procedures for retraining and maintenance of skills and expertise.

Skills for Justice define competence as "The skill, knowledge and understanding required to do a role, evidenced consistently over time through performance in the workplace."

(Skills for Justice is one of a number of sector skills councils for the UK Government responsible for the Justice sector.)

Skills for Justice have also set out five points to cover competence described as tools to assess competence. These are set out in Table 1.

There is the further argument that if an expert can satisfy the professional body of their competence, then there are no further requirements for the courts. Normally, a professional body would expect to have chartered status or its equivalent, and this status within the forensic arena must incorporate knowledge and skills as well as competence in their ability to write and deliver, if required, oral testimony to the court. There may be several professional bodies within the various disciplines covered by forensic science – for example, Royal Society of Chemistry, Society of Biology, etc. These bodies may provide the science but not all professional bodies will provide the ‘forensic’ requirements to combine the science and the legal requirements of reports/statements for the court. The United Kingdom-based Forensic Science Society (FSSoc) has recently introduced its accredited forensic practitioner status with standards equivalent to a ‘chartered’ status and time is required to see it firmly established. The FSSoc has also introduced an individual competence testing scheme which has been applied to podiatrists. It cannot and does not replace the requirements of the ISO standards but for the individual, as opposed to the organization, it provides an individual certificate of competence.

Cost of Accreditation

The cost to implement, maintain, and develop the quality system is seen as a key budgetary factor for organizations. It may be an even more significant factor for the smaller companies. The cost to development, maintaining, and monitoring a quality system is a necessary requirement but these costs can be reduced through appropriate collaboration between organizations to establish validated methods and through sharing of some quality systems information. It is common for the quality costs to a forensic science provider to be around 10–15% of running costs. As each organization is unique, it is not possible, or desirable, to attempt a ‘one fits all’ approach. There is a growing consensus that quality systems are more

detailed than necessary as an overreaction to meeting accreditation requirements. This comes at a cost, both in monetary terms and potential negative effects in efficiency of systems. A proportional balance needs to be achieved based on a proper understanding of risk management principles.

Certification and Registration

One might argue that organizations or individuals who have gone through various ‘tests’ would be placed on a register either internally within the organization or as a public-facing register. This is certainly true for medical practitioners who register with the General Medical Council and lawyers who, in England and Wales, register with the Solicitors Regulation Authority or Bar Standards Board. There is no such forensic practitioner register. Within the United Kingdom, there was a Council for the Registration of Forensic Practitioners but this was closed in March 2009. Further, there is no legal requirement for a forensic organization or forensic practitioner to be registered. However, the court will wish to satisfy itself as to the reliability of the witness. So the qualifications, experience, competence, use of validated techniques, publications, etc. are all considerations for the court to understand before allowing the individual to be accepted as an expert witness. A register certified by a professional body with chartered status can be used to capture many of these requirements and therefore be helpful to the court. There are some specific areas such as drug analysis which require legal authorization.

Validation

ILAC-G19-2002 section 5.4.1 stipulates that all technical procedures used by a forensic science laboratory should be fully validated before being used on case work. There are many techniques used by forensic practitioners and many of these have been used for years. However, these may not necessarily have been validated and have simply been used and adopted over time as the way things are carried out.

Those working in the forensic arena have been using numerous techniques for years from various spot tests to blood grouping to footwear comparisons. These techniques have

Table 1 An illustrative five-point quality management system

Type of test	Area of competence tested
1 <i>A case review.</i> Between line manager and practitioner to assess what was done by the practitioner, decision-making processes, what could have been done better, review of forensic strategy, overall outcome of items taken for analysis, etc.	Knowledge and understanding
2 <i>Simulated competence test.</i> A simulated competence check providing the practitioner with a scenario with known outcomes and based on the relevant National Occupational Standards (NOS). This can include ‘blind trials’ where known items are entered into the workflow unknown to the practitioner	Knowledge, understanding, and skills
3 <i>Observation (site visit).</i> Line manager observes the practitioner undertake an agreed number of tasks to assess competence against agreed NOS	Skills, knowledge, and understanding
4 <i>Knowledge test.</i> Practitioner sits a written knowledge test which is marked by a competent peer or line manager to ensure the practitioner has knowledge required to perform role competently	Knowledge and understanding
5 <i>Dip-sampling.</i> A set number of ‘work products’ are sampled randomly every month to ensure consistency in competent delivery of work tasks	Consistency of performance over time

been written about and handed down but whether they have been specifically validated as an appropriate technique may now be the question. From the court perspective, it does not want advances in scientific thinking and technology to prevent best evidence being presented before the court. However, the court needs assurance that the technique, approach, and evaluation are in line with the profession's thinking and accepted doctrine. Consequently, the lack of validation could contribute to evidence being deemed inadmissible due to it being seen as unreliable. However, if the court is made aware about any limitations and error rates, then it is in a better position to make a judgment. There is therefore a link between accreditation and validation. If a technique is used by the organization, and that part of the organization is within the accreditation scope, then the accreditation requires the technique to be validated. This is obviously right and proper but notwithstanding this, historically there has been an element of 'grandfathering' existing techniques.

Courts' View

It is interesting, if not worrying, to note that even though the forensic practitioner is accountable to the court, the court does not currently require an organization or individual to be accredited to any national or international standard to enable them to be allowed to present their evidence to the court. Consequently, there is currently no requirement by the courts to accept only evidence from accredited organizations. In other words, the courts need to fully understand that it is the organization which is accredited and their working scientists, as employees, will be authorized and must be competent, the key issue being that this organizational accreditation does not give them automatic 'expert' status. The individual's behavior and ability to evaluate, assess, and interpret are inextricably linked to the effective forensic practitioner presenting reliable evidence. One overriding difficulty which has not yet been satisfactorily resolved is the proof of competence in the delivery of evidence in court. With so many variables, there is no established acceptable manner in which to fully assess the delivery of oral evidence. It is true to say that the courts are now becoming more cognizant of the accreditation/competence activity from the forensic community and accreditation may be a requirement by some who instruct a forensic provider – organization or individual.

Finally, the important aspect of individual competence coupled with the use of validated techniques, quality systems, and audits all contribute to the stamp of accreditation which should provide reliable professional and expert evidence to the investigation and courts.

Certification

J Robertson, University of Canberra, Canberra, ACT, Australia
MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction – What Is certification?

Certification involves some mark of formal confirmation that a level of knowledge or conformance with agreed standards has been reached or demonstrated by a person, an organization, or an object. Some form of external review or assessment is often required for certification to be awarded. Accreditation is the term for an organization's certification.

First-, Second-, and Third-Party Certification

First-party certification is where an individual or organization that provides goods or services offers assurance that it meets agreed levels and/or standards. Second-party certification is where an individual or organization belongs to a professional organization that provides confirmation that standards are being met. The International Association for Identification (IAI) in the United States or the Forensic Science Society (FSSoc) in the United Kingdom offer second-party certification to individuals. Finally, with third-party certification, assessment of an individual, organization, or product is carried out by an independent body. NATA in Australia, the American Society of Crime Laboratory Directors – Laboratory Accreditation Board (ASCLD-LAB), and Forensic Quality Services (FQS, which was recently acquired by the American National Standards Institute – American Society for Quality (ANSI-ASQ) National Accreditation Board) in the United States, and the UK Accreditation Service (UKAS) in the United Kingdom are examples of third-party agencies through which forensic organizations can become accredited.

Certification of Individuals

Certification is normally not a legal standard or requirement. Certification for individuals engaged in a professional activity will normally be administered by a relevant professional body, typically of peers. However, there is an increasing trend toward certification, which lies below full professional status certification, with certification of differing standards being offered by academic, training, and commercial organizations. With the latter, certification of the individual may be limited to use of a specific product; this is particularly common in the information technology industry.

Where a regulatory authority establishes a formal requirement for certification, as a practice requirement, this is usually called a licensure. A license is an official 'permission to practice' a profession that has the potential to affect public good and, therefore, is seen by governing bodies as needing regulation. Medical personnel, pilots, accountants, geologists, and many other professionals require licensure before they are allowed to

practice; licensure requirements also vary by country. Education, a period of training, and a documented demonstration of expertise, such as a test, are typically required for a license to be issued.

Certification versus Accreditation

Some confusion can exist between certification and accreditation. While it is possible for an organization to be certified for a particular purpose, in the forensic enterprise, organizations more often seek to be accredited. Indeed, various bodies offer accreditation to certifying organizations. In this way, the certifying body is able to demonstrate that it is meeting agreed-upon standards. This in turn means that the client or purchaser of a service offered by an individual or a product can have confidence that that service or product meets at least the minimum levels of compliance offered by the relevant certification.

For example, the US-based Institute for Credentialing Excellence in 1987 created the National Commission for Certifying Agencies (NCCA). The NCCA aims to ensure the health, welfare, and safety of the public through the accreditation of certification programs or organizations that assess professional competence. NCCA has accredited over 200 programs from more than 100 organizations. Interestingly, the only forensic group certified by this organization is the National Association of Forensic Counsellors.

The American Academy of Forensic Sciences (AAFS) recognized in the mid-1990s that existing certification through forensic boards varied in relation to quality and standards. The AAFS took the position that an important role for a professional body was the monitoring of quality and consistency of application by relevant boards and that some form of accrediting certifiers was necessary. With funding support from the US National Institute of Justice (NIJ), the Forensic Specialties Accreditation Board (FSAB) was established and was incorporated as an independent organization in 2000.

FSAB performs a role similar to that of NCCA but specializes in forensic disciplines. FSAB argues that because of the unique nature of forensic disciplines and the relatively small number of specialists credentialed (certified) by each organization, the forensic boards would be better assessed by an accrediting organization that is dedicated to this particular task and has a thorough understanding of the forensic disciplines. FSAB has accredited 16 Boards since 2004. Accreditation is for 5 years and four of the Boards have been through a second round of accreditation. The first Board to receive accreditation was the American Board of Criminalistics (ABC); the role of the ABC is discussed in more detail later in this article.

FSAB publishes Standards for Accrediting Forensic Specialty Certification Boards. Included in the requirements for the

certifying body are that the scope of the program is clearly defined and available to the public through a website. The site has to provide information including the following:

- a description of the organizational structure and legal status of the organization;
- the purpose of the certification program;
- a study guide to give an outline of the scope of the program, including the areas covered by the certification and the required knowledge, skills, and abilities of applicants;
- the minimum education, training, and experience required for applicants;
- a description of the procedures used to test or evaluate the knowledge, skills, and abilities of the applicant;
- the standards and rules for granting, maintaining, suspending, and revoking certificates;
- the criteria used for the evaluation of any required training program(s)/course(s), and/or trainer(s);
- the application form and an outline of the application process (The application must include a statement that the applicant agrees to comply with the requirements for certification.);
- a disclosure of any exceptions that may be made to the standards usually applied to certification of an individual and the rationale for that (e.g., waiver of a degree requirement);
- a full description of the recertification procedure for certificants, including the minimum standards required and any alternate pathways for recertification (e.g., examination in lieu of sufficient continuing education requirements);
- a description of restrictions or limitations on the use of the certification body's marks, and on ways of referring to the certificates granted;
- a directory of certified individuals; and
- an outline of all substantive changes to the standards used to credential (evaluate), test, and certify applicants.

Certification standards include general requirements for initial professional development or training, competency and examination, ethics and professional standards, adherence to continuing professional development (CPD), and relevant work experience.

In Australia and New Zealand, an organization called JAS-ANZ (Joint Accreditation System of Australia and New Zealand) runs five programs under the headings of Management Systems Certification, Product Certification, Personnel Certification, GHG Validation, and Verification and Inspection. JAS-ANZ also offers accreditation to Conformity Assessment Bodies (CABs) around the world.

International Certification Schemes

Forensic certification schemes for the certification of forensic partitioners exist in many parts of the world.

The American Board of Criminalistics (ABC) is an example of a voluntary process based on peer review. The objectives of its program are the following:

- to set and measure professional levels of knowledge, skill, and abilities;
- to guide professionals in the attainment of professional levels of competence;
- to provide a means of evaluating the competence of practitioners; and
- to provide a formal process for the recognition of practitioners who meet the professional level of competence.

Some schemes place more emphasis on work history and employment-based evidence of competence, whereas others are more independent with a qualification- and/or an examination-based assessment. For example, the ABC scheme is awarded on the basis of individuals holding a relevant degree, having a minimum of 2 years of laboratory or teaching experience, and providing proof of completion of an ABC examination.

Another organization based in the United States, the IAI, offers certification in the following areas:

- Bloodstain Pattern Examiner Certification
- Crime Scene Certification
 - Certified Crime Scene Investigator
 - Certified Crime Scene Analyst
 - Certified Crime Scene Reconstructionist
 - Certified Senior Crime Scene Analyst
- Footwear Certification
- Forensic Art Certification
- Forensic Photography Certification
- Forensic Video Certification
- Latent Print Certification
- Tenprint Fingerprint Certification

A mixture of education, experience, and testing leads to these certifications being awarded.

The Council for the Registration of Forensic Practitioners (CRFP) in the United Kingdom was established in 1999 in response to concerns about miscarriages of justice and the role of forensic evidence. Its aim was to create a credible professional register to enhance public confidence and the credibility of forensic practitioners. The scheme was funded by the government and was expected to become self-funding through registration fees; the latter goal was never achieved and the program was closed in 2008. Although the scheme for certified registered practitioners was not formally a certification scheme, in practice, the intention was that it would act as a professional register with entry controlled by qualification and demonstrable proof of attainment of standards of competence.

The office of the Forensic Science Regulator was established in the United Kingdom shortly after the CRFP was closed. The role of the regulator includes provision of independent advice on quality standards including

- identification of the requirement for new and improved quality standards;
- development of new standards where necessary;
- provision of advice and guidance so that service providers will be able to demonstrate compliance with common standards, for example, in procurement and in the course; and
- existence of satisfactory arrangements to provide assurance and monitoring of the standards.

The regulator has stated that a formal accreditation pathway is the best way for sole practitioners to demonstrate compliance with common standards, rather than through a registration process.

The UK-based FSSoc has introduced a form of certification through its Chartered Forensic Practitioner Status program. Practitioners are eligible to apply if

- they regularly attend court;
- their professionalism can be verified by current references including their line managers' endorsement of competence; and
- they can demonstrate CPD for a period of not less than the previous 3 years.

The program caters for sole or individual practitioners who meet all of the above criteria and who have the FSSoc Certificate of Competence of the FSSoc postgraduate diploma.

In Australia and New Zealand, the Australian and New Zealand Forensic Science Society (ANZFSS) also ran a registered practitioner scheme for a number of years before closing this program largely because of a lack of interest. No registration or certification scheme exists for laboratory forensic scientists. However, The Australasian Forensic Field Sciences Accreditation Board (AFFSAB), which sits in the Australian and New Zealand Police Advisory Agency (ANZPAA), accredits or certifies individuals in the fields of crime scenes, fingerprints, and firearms examinations. Application criteria for the crime scene category include holding the Diploma in Public Safety (Forensic Investigation) or equivalent and

- four years of conducting scene investigations of major/serious and complex crime and incidents;
- experience in court testimony and completion of the NIFS Expert Evidence Workshop (or jurisdictional equivalent);
- completion of training according to jurisdictional requirements; and
- completion of subdiscipline training in one or more of the following specialized areas
 - fire investigation
 - toolmark comparison
 - shoe and tire comparison
 - bloodstain pattern analysis
 - hair and fiber analysis
 - vehicle identification and number restoration
 - postblast investigation
 - clandestine laboratory investigation.

For certification and recertification, applicants must demonstrate currency within a crime scene area and competency including annual proficiency testing.

Certification Overview and Conclusions

Irrespective of the specific scheme or program, they all share common objectives and features. Primarily, certification is aimed at the level of the individual and not the employer organization. Professional level certification is most often

offered through professional member organizations and is voluntary. However, in some countries, certification is more formal albeit falling short of formal regulation. Certification is usually for a defined period of time and recertification requires individuals to demonstrate current competence including participating in relevant proficiency tests. A common element is demonstration of commitment to CPD.

Professional certification should not be confused with a level of academic qualification, where certificates may be awarded for courses ranging from only limited study and at an elementary level through to postgraduate study. There is an increasing trend toward awarding a certificate for as little as simply attending a training program; hence, genuine post-nominal certificates may become devalued. Many law enforcement agencies require certificates of attendance for training courses and this may add to the notion that the attendees are 'certified.' Although many professional certification programs are significant and serious, their voluntary nature can be seen as a potential weakness in that not all practitioners will choose to become certified. Although legal systems and courts may choose to consider professional certification in assessing the status of an expert as a witness, this has not been normally mandated. This is contrast to many other professions where academic qualifications are not sufficient in themselves for a person to be allowed to practice at a professional level, such as in medicine or law. The forensic science profession may have to consider in the future some form of mandatory postqualification certification with formal regulation.

Certification of Objects

Certification may also be offered for a particular product where the product is determined to have met standards, passed performance tests, and quality assurance tests relevant to its intended use. These standards may be required in contracts, regulations, or specifications, such as building or electrical codes, national test standards, or a set of regulations.

Introduction

Forensic science has made a significant contribution to the investigation of crime and the administration of justice and is well established within these processes. Additionally, in recent years, popular media have substantially increased the profile of the field. Reliance on forensic science for the purposes of identification has also been highlighted globally by its application in the aftermath of mass disasters and terrorist acts, with forensic technologies being widely applied to the identification of victims and, in the case of terrorist attacks, identification of the perpetrators.

While the contribution that forensic science makes to reliable justice outcomes is undeniable, its application requires a thorough understanding of the discipline being applied and its potential pitfalls. Similar to any tool in the investigator's kit, without the requisite expertise and relevant support systems, forensic results may be misapplied or results misinterpreted.

In order to minimize the risk of errors, forensic facilities have developed a quality assurance program for all forensic processes. The relationship between the forensic process (the application of scientific methodology within a laboratory) and quality assurance processes (accreditation, certification, and standardization) is demonstrated in [Figure 1](#).

Forensic laboratories seek accreditation from testing authorities to ensure compliance with national or international standards for laboratory practice. As part of this compliance, laboratories have documented practices and procedures (methods) that specify the conditions under which examinations shall be applied, conducted, interpreted, and reported. These methods should be based on published peer-reviewed research and subject to in-house validation or verification.

Forensic practitioners themselves require some form of certification, either through authorization by their facility to carry out specific classes of examination and analysis (the methods) or through qualified membership to a group or society. Certification schemes usually require ongoing assessment of the practitioners' performance within their areas of expertise.

Although each laboratory maintains a quality assurance program, variations in practices and procedures are not

uncommon. In addition, in circumstances where a particular specialized expertise not available through an accredited forensic facility is required to assist in an investigation, investigators may seek the services of experts from other service providers such as a University, Museum, or private forensic service provider. Such services may fall outside the established quality controls that exist in forensic facilities, and therefore, may be unlikely to be covered by accreditation or certification. This may also result in variations in practice.

Such variations may impact on the results obtained from an examination, or the way a result is interpreted and reported to an investigator or a court of law. The ramifications of variations may be significant: a perpetrator may escape justice or an innocent person may be unjustly punished.

The increased exchange of forensic evidence and information between states and nations highlights the role of common standards for forensic service providers in order to avoid uncertainty regarding the way in which an item has been handled, the methods that have been used, and how the results have been interpreted. The use of standards ensures the continuing reliability and quality of forensic science at an international level.

Why Standards Are Required?

Unreliable justice outcomes damage public faith in the legal system and may also lead to legal challenges as to the accuracy of forensic evidence. In the following case studies, the focus is on cases involving DNA evidence; however, the implications of the cases with respect to the lack of national or international standards are more generally applicable to forensic science practice and procedures. A review of these cases illustrates that the failings have generally been the result of breakdowns in processes or procedures, and not of failures of the scientific technique.

Case Study 1

Over a 7-year period, millions of Euros and hundreds of thousands of police hours were spent searching for a female suspected serial killer in Europe. The suspect was linked through DNA matches between a series of 40 crime scenes in Germany,

Figure 1 Relationships between the forensic process and quality assurance program, outlining the role of standards.

Austria, and France. The DNA was linked to the murder of a female church warden in 1993, the murder of a 22-year-old policewoman in 2007, and the execution-style killings of three Georgian car dealers. Suspicions regarding the possibility of contamination arose when the number and diversity of linked crimes increased. Many of the cases were solved, but no female suspect with a matching DNA profile could be located. The initial doubts were confirmed when the same DNA profile was found during an investigation into the identity of a burned body in France that was thought to belong to an asylum seeker who had disappeared in 2002. Using swabs (pooled together) of the missing man's collected fingerprints, the DNA was extracted to produce a profile that was found to match the female suspect's DNA profile from the linked cases. Investigators began to suspect that batches of cotton swabs had been contaminated with DNA from an unknown source during the manufacturing process. Further products have since been identified as having contaminations resulting from the manufacturing process. The supposedly uncontaminated sterile swabs are used by police forces in several European countries.

Case Study 2

In 2006, a 48-year-old woman fell unconscious in a nightclub in Melbourne (Australia). Although she had no memory of being sexually assaulted, there were concerns that she may have been drugged and assaulted. Vaginal swabs were collected from the alleged victim at a designated facility in a hospital. When analyzed at a forensic laboratory, a DNA match was reported that linked biological material on the alleged victim's sample to the reference DNA profile from an earlier incident involving a 19-year-old male (although this earlier incident was determined as no offense having occurred). Police investigating the matter became concerned that there was no supporting evidence to link the male suspect to the alleged victim and queried the laboratory about the possibility of cross-contamination

between the two cases. The forensic facility discounted the possibility on the basis of the two samples being examined by different technicians, at different times, and in different areas of the laboratory, and of their being processed in different batches. At the trial, the young male was convicted of the sexual assault and sentenced to 6 years imprisonment. The case was appealed. The prosecution investigation, in preparation for the retrial, revealed that the DNA samples relating to the earlier case were collected approximately 28 h before the alleged victim's vaginal swabs were collected, and by the same doctor in the same examination room within the same designated facility. It was at this point that the high possibility of contamination of the alleged victim's vaginal swab was realized and a subsequent inquiry found that contamination at the point of sample collection in the hospital was the most likely explanation. When the matter came before the court in 2009, it was accepted that a miscarriage of justice had occurred and a verdict of not guilty was entered.

The cases above provide examples where compliance with national or international forensic standards could have a role in minimizing the avoidable waste of investigational resources and poor justice outcomes. While there may be variations in practices across jurisdictions based on the legal environment and technical application, the scientific basis for the methodologies and procedures that are utilized is universal. This universal approach should apply to the entire forensic process, from the identification and collection of items and samples, including packaging and sample integrity, through to analysis, interpretation of results, and reporting. This is where defined forensic standards can provide guidance in acceptable practice for scientists, and confidence in the expert opinions provided for the judicial process.

The United States National Academy of Sciences Report 2009

The report published by The National Academy of Sciences in 2009, (under a direction from US Congress) '*Strengthening Forensic Science in the United States: A Path Forward*' (the 'NAS Report'), highlighted problems that existed in the field of forensic science within the United States and called for the establishment of a National Institute of Forensic Science to develop forensic science standards to address the identified problems.

Although the NAS Report focused on the situation with respect to forensic science practice in the United States, it is obvious that the issues identified and recommendations provided apply globally and have implications for all forensic practitioners.

In particular, the NAS Report stated that operational principles and procedures for many forensic science disciplines were not standardized, either between or within jurisdictions. Furthermore, where protocols aimed at facilitating consensus are in place, such as Scientific Working Group standards, they are not intended to be enforceable. This is seen to pose a threat to the quality of forensic science practice, reinforcing the need for systematic changes, including establishing enforceable standards, to promote best practice, ensure consistent outcomes and reliability of forensic science as a whole. Many disciplines have already taken steps to identify where improvements in their fields can be made.

The Purpose of Standards

Standards provide guidance and set out specifications and procedures that ensure that products, services, and systems are reliable and perform consistently to an expected level, and that confidence can be placed on their outcomes. They are regularly reviewed to ensure that they keep pace with new technologies.

As voluntary consensus documents the application of standards is by choice unless their use is mandated by government or specified by a contract. Standards may also be applied by means of a voluntary industry code, or by quasi-regulation such as a standard endorsed by government.

Standards are intended to be practical. While they may exceed the minimum expectations of performance or practice, they are not intended to be difficult to comply with, based as they are on sound scientific principles, the experience of practitioners, and the expectations of the end user.

Standards define the level of expectations for a quality service. In the case of forensic standards, the end users are usually law enforcement agencies and the justice system, but the outcome of any investigation or trial impacts on society, either as a whole or as individuals. Society has an expectation that services and products comply with national or international standards; forensic science laboratories should not be exempt from the same expectations.

Advantages of Recognized Forensic Standards

Forensic science standards provide the following benefits:

- consistency of practice within laboratories;
- consistency in procedures across laboratories and agencies;
- defined standards of reliability and quality for all forensic practitioners;
- standard practices that private practitioners, smaller agencies, and institutions will be able to refer to in order to ensure that their work meets the required standard for acceptance in a judicial setting; and
- judicial confidence in forensic science laboratory output.

Compliance to a platform of relevant standards for forensic science disciplines ensures that methodologies are robust, repeatable, and validated, and that training as well as experience across laboratories is consistent. This has a direct bearing on the quality of scientific evidence presented in the courts, and reduces the risk of poor justice outcomes, such as exemplified in the case studies mentioned previously. Consistent and accepted forensic standards will benefit all users of the judicial system, including members of the public as well as investigators, legal practitioners, and forensic scientists.

Recognized standards facilitate professional mobility. This is a direct consequence of standards and standardization. Professional mobility has many advantages in times when a rapid response is required to scenes of major crime or disaster, which is beyond the means and capabilities of any one laboratory (e.g., multiagency responses to mass disasters or terrorist acts). Besides reducing resource requirements, this also enhances forensic capacity and capability, and the development of individuals and forensic disciplines.

The existence of forensic science standards benefits smaller specialized forensic service providers and individual practitioners who provide niche forensic services to the public and the judicial system. These service providers are often unable to meet the cost of external accreditation and are looking for guidance in developing procedures and protocols that would ensure legal acceptability and consumer confidence, within the constraints of their environment. Forensic science standards provide the guidance in developing practices and procedures that specialized service providers require.

Forensic science standards reduce the risk of miscarriage of justice and, therefore, have the potential for significant savings to society with respect to the costs of retrials or other litigious processes. Additionally, standards reduce the duplication of effort that occurs in establishing concurrent methodologies.

Global Standard Environment

International Standards

Accreditation helps establish trust in the validity of the basic analytic methods used in forensic laboratories by offering evidence that laboratory activities are performed in accordance with relevant standards and applicable guidelines. Most accredited forensic laboratories are assessed against ISO/IEC 17025 'General requirements for the competence of testing and calibration laboratories,' published by the International Organization for Standardization (ISO). The objective of this Standard is to specify the general requirements for the competence of a laboratory to carry out tests and calibrations, including sampling, performed using standard, nonstandard, and laboratory-developed methods. Although specific in parts, the requirements of ISO/IEC 17025 are generally at an organizational level and specify laboratory management requirements, with an emphasis on policy and documentation. As such, ISO/IEC 17025 does not address the requirements for sampling and testing in a forensic laboratory that serves the justice system. To address this gap, some accreditation bodies have developed field application guides that provide specific guidance to forensic laboratories; however, the focus of such guides is on laboratory procedures rather than crime scene procedures. The International Laboratory Accreditation Cooperation (ILAC) is an international cooperation of accreditation bodies, which promotes and harmonizes laboratory and inspection accreditation practices. ILAC also publishes guidelines for forensic science laboratories in the application of ISO/IEC 17025.

In the absence of any specific standard covering the collection and examination of material for forensic purposes, The United Kingdom Accreditation Service (UKAS) is developing accreditation for the scene of crime investigation against the international standard ISO/IEC 17020 – General criteria for the operation of various types of inspection bodies performing inspection. The use of ISO/IEC 17020 for forensic accreditation takes the relevant aspects of the Standard and applies it to crime scene investigations. However, although ISO/IEC 17020 may be generally applicable to crime scene examination, it is unlikely that it can be extended to forensic laboratories as it is aimed at criteria for inspection bodies

in the examination of 'materials, products, installations, plant, processes, work procedures, or services' to provide certification.

ISO/IEC DIS 27037: Information technology – Security techniques – Guidelines for identification, collection, acquisition, and preservation of digital evidence.

In 2008, the ISO/IEC Joint Technical Committee commenced the development of a standard for 'Evidence Acquisition Procedure for Digital Forensics,' which will provide detailed guidance on the acquisition of electronic evidence and subsequent maintenance of its integrity. It will define and describe the process of recognition and identification of the evidence, documentation of the crime scene, collection and preservation of the evidence, and the packaging and transportation of the evidence. The aim of the standard is to provide guidance to law enforcement and digital (computer) forensic scientists to maintain the integrity of electronic evidence required for extradition between law enforcement agencies across national borders. The standard will also provide guidance to private companies that have to preserve electronic evidence to assist criminal investigations by law enforcement agencies.

North America

In the United States of America, over 385 crime laboratories are accredited by the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB), including federal laboratories, state and local agency laboratories, as well as private laboratories. Since 2004, ASCLD/LAB has provided accreditation under the ASCLD/LAB-International Accreditation Program that is based on ISO/IEC 17025, supplemented by forensic specific requirements. Since 2009, all new applications for accreditation are assessed against ISO/IEC 17025 although approximately half of the accredited laboratories continue to be assessed against a legacy system.

ASCLD/LAB also accredits forensic facilities outside the United States, including facilities in Canada, Hong Kong, Malaysia, New Zealand, and Singapore.

ASTM International (formerly known as the American Society for Testing and Materials – ASTM) publishes a range of forensic standards. ASTM is currently harmonizing their standards with ISO. The ASTM approach to forensic standards (through the work of the Committee E-30) has produced widely recognized documents as guidelines for practice or specific forensic methods. As guidelines, ASTM standards do not necessarily hold the same authority as a standard and can be quite prescriptive regarding specific processes or application. In addition, numerous ASTM forensic standards include processes that are common to many forensic disciplines (such as exhibit collection, storage, analysis, and reporting results) and, therefore, the scope and procedures covered often overlap to a significant extent.

United Kingdom

The UKAS is the sole national accreditation body recognized by the UK government to assess, against internationally agreed standards, organizations that provide certification, testing, inspection, and calibration services. Forensic laboratories in the United Kingdom are accredited by UKAS against ISO/IEC 17025.

British Standards Institution, the National Standards Body of the United Kingdom, released a Publicly Available Specification (PAS) for forensic kits. in 2012. PAS 377: Consumables used in the collection, preservation, and processing of material for forensic analysis – specification for performance, manufacturing, and forensic kit assembly.

The Forensic Science Regulator sets quality standards for forensic science used in the criminal justice system in England and Wales. The Regulator continues to publish quality guides for forensic science although the guides are not published as Standards and, therefore, do not hold the same authority.

Manual of Regulation Part One: Policy and Principles (published for consultation): sets out the high-level principles proposed by the regulator and the methods by which the regulator intends to set and monitor quality standards in the delivery of forensic science evidence to the criminal justice system.

Codes of Practice and Conduct for forensic science providers and practitioners in the Criminal Justice System: the code of practice and conduct is based on the good practice that accredited providers are already required to demonstrate under ISO/IEC 17025.

Developing a Quality Standard for Fingerprint Examination: This position paper sets out the initial views of the fingerprint quality standards specialist group, indicates that quality standards must be developed for fingerprint examination to address the known risk of human error in this cognitive discipline.

Europe

In 2009, in order to step up cooperation in combating terrorism and cross-border crime, the European Union adopted an Act under the EU Treaty on accreditation of forensic service providers carrying out laboratory activities to ensure that forensic service providers carrying out laboratory activities are accredited by a national accreditation body as complying with ISO/IEC 17025. This Act provides a legally binding instrument on the accreditation of all forensic service providers carrying out laboratory activities for the analysis of scientific evidence.

The European Network of Forensic Science Institutes (ENFSI) is recognized as an expert group in the field of forensic sciences, which aims to ensure the quality of forensic science throughout Europe and publishes best practice manuals and glossaries of forensic terms. ENFSI encourages laboratories to comply with best practice and international standards for quality and competence assurance.

Australia

The National Association of Testing Authorities (NATA) accredits all Government laboratories against ISO/IEC 17025. To support ISO/IEC 17025, NATA developed a Field Application Document (FAD) for forensic science laboratories. The FAD provides guidance to forensic laboratories in the application of ISO/IEC 17025, but does not address the standardization of specific processes and procedures. Specific requirements, such as sample recognition and collection at a scene, appropriate sample packaging and labeling, transport of forensic samples, sample continuity, examination and interpretation of results, reporting evidence of fact or opinion evidence, are not specifically covered in either ISO/IEC 17025 or the FAD.

Figure 2 The 'core' forensic standards cover the universal aspects of forensic science practice.

Owing to a number of inadequate justice outcomes that impacted negatively on the perception of the field of forensic science, the Senior Managers of Australia New Zealand Forensic Laboratories (SMANZFL) recognized the need for a suite of agreed national forensic standards. SMANZFL, working with the Australia New Zealand policing Advisory Agency National Institute of Forensic Science (ANZPAA NIFS), developed a framework for forensic science standards via Standards Australia.

Standards Australia is recognized by the Australian Government as the peak nongovernment Standards body in Australia, develops internationally aligned standards, and is a participating member of ISO and IEC.

The Standards Australia Forensic Analysis Committee (CH-041) was established by Standards Australia in 2009. It comprises representatives from stakeholder organizations: law enforcement, forensic facilities, judicial representatives, ANZPAA NIFS representatives, educators, and testing facilities from around Australia.

The core forensic standards provide a comprehensive framework of forensic science standards that are applicable to the majority of forensic science disciplines:

- AS 5388.1 Forensic Analysis Part 1: Recognition, recording, recovery, transport, and storage of material;
- AS 5388.2 Forensic Analysis Part 2: Analysis and examination of material;
- AS 5388.3 Forensic Analysis Part 3: Interpretation; and
- AS 5388.4 Forensic Analysis Part 4: Reporting.

The core standards can then be supported by the development of discipline-specific forensic science standards in the future, referencing the core standards for the more universal aspects of forensic science practice such as collection of forensic material, examination techniques, interpretation of analytical results, and reporting of findings (see [Figure 2](#)).

Challenges in Developing Standards

Standards are not designed to replace procedure documents, laboratory methods, or facility policies. Therefore, the

challenge is to produce standards that are not prescriptive with respect to methodology, but recognize the existing accepted practice and define the expectations of reliability and consistency of the results that are obtained and reported.

In the forensic environment, this can be achieved by defining:

- the requirements for protecting the integrity of forensic material from its recognition and collection, and through subsequent analysis stages;
- the appropriate recommended practices and procedures that may be applied to the examination and analysis of forensic material;
- the required performance parameters for analytical techniques;
- the way various analysis and examination results shall be interpreted; and
- the appropriate wording to use when reporting results, conclusions, and opinions.

By not specifying detailed analytical methodology or examination procedures, standards allow practitioners to determine the appropriate method to apply to a particular forensic process, according to the practice and procedure documents approved by their facility, while still fulfilling the requirements of a standard for reliability and consistency.

Agreed standards ensure robust, reliable, and consistent results and are an important part of the quality system globally. The development of forensic standards ensures the continuing reliability and quality of forensic science and the continued confidence of investigators and the courts.

Risk Management

J Robertson, University of Canberra, Canberra, ACT, Australia

© 2013 Elsevier Ltd. All rights reserved.

Introduction – Why Do We Need Risk Management?

The events of the first decade of the 2000s including global terrorism, pandemics, the failure of much of the global banking system and major corporations, and, even governments, reinforce the inescapable truth that the world is unpredictable and it is not possible to control every aspect of life. The consequences of global events are equally difficult to predict at a local level. For example, one consequence of the global credit crunch has been a major fall in the value of property in many countries caused in part because potential buyers are unable to access funds due to lenders adopting a much more cautious approach. To use the terminology of risk management, there is a reduced 'risk attitude or appetite' on the part of lender organizations. However, the impact of this has not been uniformly felt at a more local level, with little or no impact in some countries, and a major impact on other countries.

Hence, risk is an unavoidable fact of life, in the same category as tax and death! Risk exists at a global, local, and personal level. Risk needs to be managed and this management needs to be both systematic and comprehensive. It also needs to be scaled appropriately, considering the three basic principles of risk management: likelihood, consequence, and impact. Hence, while there may be a high likelihood, if the consequence is insignificant, then the risk would be low. If the likelihood is rare, then even with a severe consequence, risk would be low. However, events such as the meltdown of nuclear reactors in Japan after the 2011 earthquake show that when a rare event happens the consequences can be critical. Where the consequence is severe and the likelihood almost certain, the risk must be treated immediately. A useful matrix showing the relationship between consequence and likelihood is shown in [Figure 1](#).

Risk management can sometimes be viewed in a narrow sense as an audit and compliance requirement for business, often with a high cost to the organization, but it is equally important to understand that there are potential benefits from effective risk management. The Institute of Risk Management (IRM) summarizes risk components as compliance, assurance, decisions and efficiency/effectiveness/efficacy, or CADE3. An appropriate and cost-efficient risk management plan can be developed if it is proportionate, aligned, comprehensive, embedded, and dynamic. A very important aspect of the latter is that risk management needs to be appropriate to the level of risk or, in other words, proportionate. Risk management needs to be aligned in a holistic and strategic way as a whole of organization commitment and it needs to be comprehensive. Finally, risk is not static. In a changing world, risk management needs to be dynamic and capable of responding in a nimble fashion to rapid change.

Defining Risk

Risk is defined in the Oxford English Dictionary as "a chance or possibility of danger, loss, injury, or other adverse

consequences." The international guide to risk-related definitions, ISO Guide 73, defines risk as "effect of uncertainty on objectives," and the IRM defines risk as "the combination of the probability of an event and its consequence." Consequences can range from positive to negative. There are other definitions of risk issued by audit organizations which further stress the concepts of 'consequence' and 'likelihood.'

Hence, common elements of risk include concepts of chance, uncertainty, probability, consequence, likelihood, and impact on outcomes or objectives. Risk can have both negative and positive consequences or, in some instances may result in uncertainty. Those risks which can only have a negative outcome are called *hazard risks*. These risks which can have a positive outcome are referred to as *opportunity risks* and these risks where the outcome is uncertain, *control risks*.

In order to understand risk it is first necessary to describe risk. [Table 1](#) shows an example of the type of information which should be analyzed in order to describe a risk.

Once a risk has been described, it is useful to then classify risk in order to consider appropriate risk treatment. There are many schemes to classify risk one of which is shown in [Figure 1](#). In this scheme, risk is classified in a matrix which considers likelihood, consequence, and impact or magnitude.

Risk Appetite or Attitude

Risk attitude is defined in ISO73 as an "organisation's approach to assess and eventually pursue, retain, take, or turn away from risk." Risk attitude or appetite will often reflect the nature of the enterprise and, to some extent, may also be influenced by the maturity of the enterprise. A highly entrepreneurial business will have a much greater appetite for risk, based on expected positive returns from opportunity risk, than a mature business, where their potential negatives may outweigh the potential positive return. For the 'forensic business,' where any error has very serious negative implications, the appetite for risk will generally be very low. However, innovation usually only comes from some willingness to accept risk. Hence, even in a risk averse industry, each risk needs to be considered on its individual merits against a whole of organization strategic position. This introduces the concept of risk or *hazard tolerance*. For example, organizations will usually have low to zero tolerance for risk associated with health and safety. As it is rarely, if ever, possible to eliminate all risk, the balance sought will be to manage risk to the lowest level that complies with the law and is cost-effective.

Risk Management Principles, Process, and Framework

ISO 31000 lists a series of principles and processes which link to an overall framework for risk management. These are shown in [Figure 2](#).

Likelihood	Almost certain	Critical	High	Significant	Medium	Low
	Likely	High	High	Significant	Medium	Low
	Possible	Significant	Significant	Medium	Medium	Low
	Unlikely	Medium	Medium	Medium	Low	Low
	Rare	Low	Low	Low	Low	Low
		Severe	Major	Moderate	Minor	Insignificant
Consequence

Table 1 Risk description

- Name or title of risk
- Statement of risk, including scope of risk and details of possible events and dependencies
- Nature of risk, including details of the risk classification and timescale of potential impact
- Stakeholders in the risk, both internal and external
- Risk attitude, appetite, tolerance, or limits for the risk
- Likelihood and magnitude of event and consequences should the risk materialize at current/residual level
- Control standard required or target level of risk
- Incident and loss experience
- Existing control mechanisms and activities
- Responsibility for developing risk strategy and policy
- Potential for risk improvement and level of confidence in existing controls
- Risk improvement recommendations and deadlines for implantation
- Responsibility for implementing improvements
- Responsibility for auditing risk compliance

Source: Hopkin P (2010) *Fundamentals of Risk Management: Understanding, Evaluating and Implementing Effective Risk Management*. London: Kogan Page.

Hopkin and the IRM provide a similar but alternative way of describing risk management, referred to as the 7R's and 4T's model.

The 7R's

1. Recognition or identification of risks and identification of the nature of the risk and the circumstances in which it could materialize
2. Ranking or evaluation of risks in terms of magnitude and likelihood to produce the 'risk profile' that is recorded in a risk register
3. Responding to significant risks, including decisions on the appropriate action regarding the following options:
 - tolerate
 - treat
 - transfer
 - terminate
4. Resourcing controls to ensure that adequate arrangements are made to introduce and sustain necessary control activities
5. Reaction planning and/or event management. For hazard risks, this will include disaster recovery or business continuity planning
6. Reporting and monitoring of risk performance, actions, and events and communicating on risk issues, via the risk architecture of the organization

7. Reviewing the risk management system, including internal audit procedures and arrangements for the review and updating of the risk architecture, strategy, and protocols

Source: Hopkin P (2010) *Fundamentals of Risk Management: Understanding, Evaluating and Implementing Effective Risk Management*. London: Kogan Page.

The 4T's of tolerate, treat, transfer, or terminate are described below.

- | | |
|--|---|
| 1. <i>Tolerate</i>
Accept/
retain | The exposure may be tolerable without any further action being taken. Even if it is not tolerable, the ability to do anything about some risks may be limited, or the cost of taking any action may be disproportionate to the potential benefit gained |
| 2. <i>Treat</i>
Control/
reduce | By far the greater number of risks will be addressed in this way. The purpose of treatment is that, whilst continuing within the organization with the activity giving rise to the risk, action (control) is taken to constrain the risk to an acceptable level |
| 3. <i>Transfer</i>
Insurance/
contract | For some risks the best response may be to transfer them. This might be done by conventional insurance, or it might be done by paying a third party to take the risk in another way. This option is particularly good for mitigating financial risks or risks to assets |
| 4. <i>Terminate</i>
Avoid/
eliminate | Some risks will only be treatable, or containable to acceptable levels, by terminating the activity. It should be noted that the option of termination of activities may be severely limited in government when compared to the private sector |

Some organizations will develop a specific *risk register*. ISO guide 73 defines this as the "document used to record risk management process for identified risks." The purpose of a risk register is to ensure there is ownership and management

Figure 2 Relationships between the risk management principles, framework, and process. From *ISO 31000 Guideline*, with permission from SAI Global under License 1108-c148 – standard can be purchased at <http://www.saiglobal.com>.

of each risk. The use of a risk register can contribute to successful risk management provided it remains an active and dynamic process. The danger is that such a document becomes too detailed and is not responsive or dynamic.

As previously stated risk management has a potential positive. Some of these benefits are:

- Fewer disruptions to normal operations and greater operational efficiency resulting in less downside of risk.
- Ability to seize an opportunity denied to competitors because a better-informed view of the management of risk is taken.
- Deliberately identifying events that will be positive during the risk assessment and deciding how to manage those events.
- Opportunity management, whereby a detailed evaluation is undertaken of new business opportunities before deciding to take the opportunity.
- Achieving a positive outcome from a situation that could have gone wrong without good judgment/risk management.
- Achieving compliance/risk assurance in difficult circumstances as an unintended/automatic consequence of good risk management.

Finally, as it is almost inevitable that risk will involve external stakeholders input should be sought from key stakeholders in developing a risk framework and treatments. A key consideration for most organizations will be to maintain business continuity and this would certainly hold true for forensic science.

Risk Considerations for the Forensic Industry

There are no requirements in ISO/IEC 17025 which specify risk management or cross reference ISO/EC 31000 Risk Management – principles and guidelines. However, by adhering to ISO/IEC 17025 many of the elements of risk management will be addressed. However it is not sufficient and organizations should also consider compliance with ISO/IEC 31000. As many forensic organizations come under the management of a larger parent organization, the risk management framework may exist at this higher level. Where there is no higher risk plan or the forensic organization is a standalone body, a risk management plan should be developed. As forensic organizations only exist to serve a larger justice system, the views of external stakeholders should be sought and risk management strategies developed to address stakeholder needs.

Conclusions

The only certainty about risk is that it is unavoidable. Risk exists at all levels from the actions of an individual to the organization and beyond. The starting point to managing risk is understanding risk and this requires comprehensive and structured analysis. Risk also does not remain fixed or static, so this analysis needs to be dynamic.

Too often, risk is seen as a negative and the potential benefits of managing risk are not recognized and, hence, not

realized. The opportunity for innovation is more likely to be recognized and realized when risk is managed. However, risk management is not free and costs need to be factored into budgets. The key to successful risk management lies in achieving a balanced approach which recognizes impact, and consequences against likelihood. Adherence to broad quality principles and ISO/IEC 17025 should assist in meeting the requirements of the equivalent risk standard, ISO/IEC 31000 but are not by themselves sufficient. Forensic science practice will by its nature present particular risks which will sometimes require very specific treatments. For example, the forensic investigation of hazardous materials and/or laboratories. However, risk management in the forensic context should be holistic and seek to address all aspects of the operation of the forensic organization.

Glossary

Benchmarking The comparison of values between entities within an enterprise.

Effectiveness The capability of producing an outcome, frequently a specific, desired effect.

Efficiency A specific or quantitative applied effort to yield a specific outcome.

Enterprise The totality of business entities, the externally visible properties of those components, and the relationships between them; this includes people, information, technology, and business operations or process.

Knowledge worker A person whose job requires extensive education, the application of theoretical and analytical knowledge, and continuous learning.

Introduction

Forensic service providers are, in essence, nonprofit, production-oriented organizations staffed largely by knowledge workers. Forensic scientists as knowledge workers take evidence and data and convert them into knowledge in the form of reports and testimony. They specialize in these transactions and, therefore, simplify them for the benefit of the criminal justice system; the investigators or attorneys do not need to find numerous individuals to conduct the specific examinations required for a case. As long as the costs of providing these services externally do not exceed the costs of their internal provision, for example, by a government forensic laboratory, then the organization can prosper. If the government laboratory costs are greater than the cost of finding private laboratories to provide services, then the organization may be reevaluated (Figure 1). For financial and political reasons (which are also largely historic), many, if not most, forensic service providers are administratively part of law enforcement agencies. Being within a paramilitary organization sets the forensic service provider's relationships with their parent agency (formally hierarchical) and other related agencies (formally or informally hierarchical, such as medical examiners or prosecutors, for example).

Comparatively, nonprofit and for-profit organizations are similar in some ways (money is an input for both) yet different (money, in the form of profits, is an output only for the private sector). Nonprofits must therefore measure success in other ways, such as 'low cost' or 'cost-effective.' Forensic service providers and their parent organizations use terms such as 'cost-effective' vaguely without reference to other disciplines which use these as well-defined technical terms in evaluative phrases or formulae. Despite the great concern and administrative angst over forensic service providers' 'performance' and 'capacity,' these metrics go undefined as industry standards. The drivers of the forensic enterprise are not well understood but research is beginning to show its similarities to other industries, as well as its differences (see the work of Speaker, for example). Despite – or perhaps because of – this lack of explicit understanding, forensic service providers are held accountable by one or more agencies for their performance based on nonstandard, ill-defined, or nonexistent criteria. Successes

and improvements go unrecognized and opportunities for advancing the mission and goals of the organization are squandered.

Knowledge Workers

The term knowledge worker was coined by Peter Drucker in 1959 to describe the then-rising group of workers whose jobs required extensive education, the application of theoretical and analytical knowledge, and continuous learning. Knowledge work, as defined by Drucker, is not experience based, as much work was up until that time, but rather is learning based. Knowledge work uniformly has high entry costs, including education, training, and credentialing. Displaced manual laborers, such as factory workers on an assembly line, therefore cannot simply move into knowledge work or services work the way displaced farmers and displaced domestic workers moved into industrial work at the turn of that age. At the very least, they have to make a major change in their basic attitudes, values, and beliefs; further, the knowledge required to conduct and advance in that career must be acquired.

Specialization of knowledge, and not generalization, is what makes it useful in the hands of a knowledge worker and the more specialized knowledge is, the more useful it becomes. Increased specialization does not imply that the knowledge will become more 'applied,' however, as many knowledge workers with highly specialized knowledge conduct very basic research, as with high-energy particle physics. With specialization come two concomitant features of knowledge workers: First, they operate in teams and, second, they have to have access to an organization. Teams balance out the necessary specializations for knowledge to be applied properly and the organization provides the basic continuity that allows the knowledge workers efforts to be converted into performance. For forensic scientists, the various investigators, laboratory colleagues, and other related organizations constitute one or more participatory teams. The continuity of the organization translates to a 'memory' of not only mechanistic procedures but a 'corporate culture' that should reflect the vision of the organization, its purpose for being (mission), and the way its members work together with others (values).

Figure 1 The model shows institutions and market as a possible form of organization to coordinate economic transactions. When the external transaction costs are higher than the internal transaction costs, the company will grow. If the internal transaction costs are higher than the external transaction costs, the company will be downsized, for example, by outsourcing. Source: Creative Commons 3.0, open source.

Although the phrase lately has been applied to all manner of employee, knowledge workers are traditionally defined by six criteria:

1. They must know what the task is and how it relates to the overall goals of the organization.
2. Knowledge workers have to manage themselves and be responsible for their own productivity.
3. Continuous improvement and innovation are inherent in their efforts; they are their own 'agents of change.'
4. Continuous learning and teaching are necessary.
5. Quantity of production is at least as important as quality of production.
6. The organization must view knowledge workers as 'assets' or 'investments' and not 'costs'; the knowledge workers must want to work for their organization above all other opportunities.

Managing knowledge workers is far more complex than typical industrial or manufacturing workers because of the above listed criteria. To properly manage knowledge workers, collaboration and professionalism must be the main emphasis. Note that these relate directly to the two previously mentioned requirements of teams and organizations. Conversely, incentives and performance measures should be de-emphasized; knowledge workers should be committed to their work and the organization's vision for its own sake. Relationships between managers and knowledge workers should be based on professionalism and mutual respect, not a structured hierarchy with incentive schemes or production quotas. All of these factors relate to forensic service providers in their work.

Effectiveness and Efficiency

Effectiveness is the capability of producing an outcome, frequently a specific, desired effect; an example would be that aspirin is effective in relieving headaches or a sports car is effective as a mode of transportation. It can be a vague concept or nonquantitative assessment; in the aspirin example, what does 'relieve' mean – No headache, less headache? And, if the

assessment is 'less headache,' how much less? Actually producing the desired effect is called efficacy, such as saying 325 mg of aspirin are efficacious for relieving a headache. Efficacy is purely the achievement of the effect, regardless of the resources expended, such as time or money. This leads to the concept of efficiency, which is being efficacious in the most economical way: the least amount of input produces a minimum of, if not more than, the desired output. Thus, what is effective (aspirin) is not necessarily efficacious (the dose may be too small), and what is efficacious (a sports car gets from point A to point B) may not be necessarily efficient (sports cars are an expensive way to travel, for example).

The effectiveness of an organization is a more complicated, dynamic concept than that of an individual. An organization's effectiveness is the combination of the effectiveness of all its individual practices and processes in addition to those external valuations that may not relate to money, people, or time, such as social responsibility, professional ethics, and corporate stewardship. Communication and leadership are deeply intertwined with organizational effectiveness. Unless the organization's vision and goals are clearly articulated to all relevant audiences, the group will not be effective. Ethics is clearly central to an organization's values as they delineate how that group wants to behave toward each other and toward others as they achieve their goals in pursuit of the vision. The relationship between goals and vision are simultaneous, dynamic, and evolving. Absent these qualitative aspects, an organization will not seem worthy of respect and integrity.

Efficiency is a useful assessment toward effectiveness of either individuals or organizations. Efficiency can be expressed as a specific or quantitative applied effort to yield a specific outcome, such as a motor vehicle's miles per gallon of gasoline rating. Higher values of output (miles) per amount of input (gas) relate greater efficiency; less is more, so to speak. Often, efficiency is expressed as a ratio of input to maximal possible output, like miles per gallon (miles:gallon) which allows for comparison between other like sources of output (other vehicles, for example) or to an idealized goal (100 mpg or an average rating for a company's fleet of cars). Thus, efficiency can be said to correspond to the ratio,

$$e = \frac{O}{I}$$

where e is efficiency, O the amount produced (output), and I the amount of resources consumed in the process (input).

The comparison of values between entities is called benchmarking. (The term *benchmarking* derives from the marks cobblers (shoemakers) made on their workbenches when measuring customer's feet for shoe patterns.) Comparisons may be made between units within a business, between businesses, or to idealized or industrial standards. The most efficient and effective performers set the industry's best practices, usually in terms of time, cost, or quality. Called 'best practice benchmarking,' this process can provide invaluable benefit for process improvement and strategic planning for an organization. Benchmarking can be a single event but is typically a periodic (quarterly or annually) part of a continuous quality process for an organization.

The FORESIGHT Project

A best practice benchmarking project for forensic service providers has been funded for several years by the National Institute of Justice through West Virginia University's Forensic Science Initiative and the College of Business and Economics (www.be.wvu.edu/forensic/foresight). The project was based on a European study called QUADRUPOL, which evaluated four European police forensic laboratories on various metrics. The QUADRUPOL report was the first report of its type and required a central tenant in benchmarking: Standard metrics. All of the laboratories participating in QUADRUPOL had to submit their data under standardized definitions; without this requirement, any data would be incommensurable and perhaps misleading. For example, if Laboratory A reported a cycle time (or turnaround time, the amount of time required to complete a case) measured from the date of the first submission of evidence to the date the report (signaling the start of the casework) was issued, but Laboratory B reported their cycle time as the date of the last submission of evidence to the date of reporting (reasoning that the casework cannot be complete unless *all* of the evidence was submitted), the two numbers would be very different and could not be compared. The FORESIGHT Project took the QUADRUPOL report and refined the definitions as well as added new ones based on International Laboratory Accreditation Cooperation, creating a Laboratory Reporting and Analysis Tool spreadsheet to facilitate data entry.

After an initial examination of mission, vision, and values of the participating laboratories in the FORESIGHT study, several common themes emerged that led to a listing of goals. The key performance indicators (KPIs) related to these goals permitted the evaluation of performances by individual laboratories to fall into a series of categorical measures. Analysis is conducted by faculty at the WVU College of Business and Economics in collaboration with the participating laboratories. Forensic organizations across the United States and in Canada participate in the FORESIGHT Project, which is free to any forensic service provider who submits data. Participant laboratories already have seen the benefit of benchmarking and, with additional data, time series and trends can be calculated. Speaker gives a good accounting of how these kinds of measures can be used to generate KPIs for forensic laboratories to measure and evaluate effectiveness and efficiency.

Glossary

Clandestine laboratory ('Clan Labs') Setting up of equipment or supplies for the manufacture of illegal compounds such as drugs or explosives.

Confined space An enclosed or partially enclosed space that is not intended or designed primarily for human occupancy, within which there is a risk of one or more of the following: (a) an oxygen concentration outside the safe oxygen range. (b) A concentration of airborne contaminant that may cause impairment, loss of consciousness, or asphyxiation. (c) A concentration of flammable airborne contaminant that may cause injury from fire or explosion. (d) Engulfment in a stored free-flowing solid or a rising level of liquid that may cause suffocation or drowning.

Dynamic risk management The continuous assessment of risk in the rapidly changing circumstances of an

operational incident, in order to implement the control measures necessary to ensure an acceptable level of safety.

Hazard The potential for a substance to cause adverse effects.

Hierarchy of control measures Ranking of measures taken to prevent or reduce hazard exposure according to effectiveness, from the most effective measures that eliminate hazards to the least effective, that achieve only limited protection.

OHS policy A policy document indicating an organization's commitment to OHS, its intentions, objectives, and priorities and identifying roles and responsibilities.

Risk The likelihood of injury or illness arising from exposure to any hazard(s) and the magnitude of the adverse effect.

Occupational Health and Safety Policy

The legislation in many countries places the onus of responsibility on employers to provide a healthy and safe working environment under occupational health and safety (OHS) legislation and common law. Employers should ensure that all managers, supervisors, and staff are aware of their OHS responsibilities. Management leadership can positively influence OHS outcomes for an organization.

Workplace health and safety is an ongoing process. Subject to the legislative requirements of each jurisdiction, in most instances a documented OHS policy is required. The development of such a policy requires the commitment of both staff and management. Once commitment has been achieved, the OHS policy should be developed with involvement from all stakeholders, and promulgated.

The OHS policy should:

- articulate the organization's commitment to OHS;
- indicate that sufficient resources (both financial and personnel) will be provided to promote and maintain OHS standards and meet OHS requirements;
- outline the organization's intentions, objectives, and priorities OHS;
- describe in broad terms the means by which the objectives will be met;
- identify the roles and responsibilities of management, supervisors, and staff in meeting OHS requirements; and
- be signed off by the most senior manager of the organization, reflecting the importance of the policy.

The OHS policy should be reviewed periodically to ensure its currency.

The OHS policy is, however, only one part of an appropriate OHS strategy for a forensic organization. The OHS policy

must be underpinned by risk assessments and incident/accident reports that enable the organization to assess its OHS exposure, to meet legislative requirements such as reporting obligations, and to respond to risks appropriately.

An organization can develop a list of the main hazards that its staff are likely to be exposed to in the course of their duties, utilizing OHS reports, incident/accident reports, and previous risk assessments. Prioritizing the main health and safety issues allows the organization to develop appropriate action plans to meet the objectives of its OHS policy.

Forensic organizations may consider integration of some OHS requirements with their quality assurance system. Many laboratories effectively use their quality system to embed OHS requirements in their documented procedures, to review OHS hazards as part of a periodic audit program or to manage elements of their OHS action plans through their corrective action system. OHS, like quality, can then be viewed as an important yet integrated component of an effective management system.

Risk Assessments

Once potential OHS hazards have been identified, forensic organizations should evaluate the likelihood of injury from the interaction to the hazard and the magnitude of the adverse effect. The process of risk assessment will be very useful for managing potential OHS hazards within the facility and the expected external work environment. The purpose of the risk assessment process is to ensure that all workplace hazards have been identified, recorded, assessed, controlled, and reviewed. The desired outcome of this process is to eliminate, as far as practicable, the risk of injury or illness to personnel, damage to property, and damage to the environment. The process of developing risk assessment is often better suited to the

known work environment. An OHS assessment of an office or laboratory can quickly identify specific hazards that may require attention. Obviously, this works well for the office and laboratory environment within one's control; however, each external scene will be different.

It is important that the range of potential hazards in external crime scenes and work environments is considered. While some risks can be grouped and managed collectively, the specific hazard and risk mitigation and control will vary from scene to scene given the circumstances. Given this, forensic practitioners should have an ability to undertake dynamic risk assessments, or 'risk on the run' as it is known in some jurisdictions.

Dynamic Risk Management

Dynamic risk assessments are conducted by a forensic practitioner as part of the attendance and examination process. In some instances, such as attendance at a clan lab, a person may be designated as the Site Safety Officer and have carriage of this as well as health and safety for all personnel at the site. Practitioners should be trained to assess the risk given the circumstances at the time, considering the actual hazards present at a crime scene.

A designated forensic practitioner or Site Safety Officer should undertake a quick reconnaissance of the crime scene to ensure the safety of forensic practitioners and others working at the scene. A review of the scene should be repeated whenever the situation at the scene changes. This could involve a visual inspection without entering the crime scene, and asking a number of questions. For example:

- Does the crime scene involve structures that are now unstable?
- Has confirmation been obtained from the Fire Brigade or other emergency responders that power, gas, and water to the site have been turned off?
- Is there adequate shelter so that practitioners can rest without succumbing to environmental stressors such as heat, cold, wind, or rain?

It is important to close the loop, and incorporate any strategic elements of each dynamic risk assessment in OHS policy and planning. After each incident, any relevant information obtained during the dynamic risk assessment should be recorded and collated for strategic analysis.

Hierarchy of Control Measures

Within OHS, there is a 'hierarchy of control' designed to mitigate or resolve a risk deemed unacceptably high.

The hierarchy of control is a sequence of options which offer a number of ways to approach the hazard control process. Various control options may be available. It is important to choose the control that most effectively eliminates the hazard or minimizes the risk in the circumstances. This may involve a single control measure or a combination of different controls that together provide the highest level of protection that is reasonably practicable.

1. Eliminate the hazard. If this is not practical, then:
2. Substitute the hazard with a lesser risk. If this is not practical, then:

3. Isolate the hazard. If this is not practical, then:
4. Use engineering controls. If this is not practical, then:
5. Use administrative controls, such as safe work practices, instruction, and training. If this is not practical, then:
6. Use personal protective equipment (PPE), such as gloves, eye protection, boots, and respirators.

It is important that management and staff discuss and consult, where possible, during all phases of the hazard identification, risk assessment and risk control process.

Examples

1. If an organization is considering purchasing a piece of analytical equipment, and two products have the same capabilities but substantially different noise levels during operation, the organization may consider the noise level of the equipment during procurement, and opt for the quieter system. This example demonstrates the principle of eliminating the hazard at source, which is the most effective control measure, when compared to training and provision of PPE such as hearing protection.
2. In the case of a fire scene of a building, applying a hierarchy of control approach, it is first necessary to consider the elimination or substitution of hazards. In a fire scene, this is not possible. It is, however, possible to isolate the scene to prevent danger to the public and to maintain the integrity of the scene. Power, water, and gas to a building should be disconnected prior to entering the site. A structural engineer's opinion may be necessary prior to entry to the building. Safe entry and exit to the site can be established. Other administrative controls, such as briefing practitioners and maintaining records of the entry and exit of personnel, may be applied. Finally, practitioners can be prevented from entering the fire scene unless utilizing the appropriate PPE.

Specific Laboratory Hazards

The likely hazards within a laboratory environment include the following.

Chemicals

Chemical exposure may occur through inhalation, skin absorption, or direct ingestion and, once absorbed, are either stored in a particular organ or tissue, metabolized, or excreted. The effect of a chemical on a person is dependent on a number of factors such as duration and frequency of exposure, concentration of the chemical, and an individual's metabolism. A synergistic effect may occur when the undesirable effects of one substance are intensified if exposure has occurred to another substance.

Some nanomaterials exhibit different chemical properties compared to what they exhibit on a macroscale. As this is a relatively new field, there is insufficient knowledge regarding the hazards posed by nanomaterials. The potential hazards associated with nanomaterials may include increased reactivity because of their increased surface-area-to-volume ratio, the ability to cross some of the body's protective mechanism, and the lack of the body's immunity against such small particles. Because of this lack of knowledge, the suggested control strategy to

be used when working with nanomaterials should be 'as low as reasonably achievable' (ALARA) approach to reduce exposure.

The effects of chemicals on the body may be categorized:

- poisonous or toxic chemicals are absorbed into the body and exert either an acute or short-term effect, such as headache, nausea, or loss of consciousness, or a long-term effect such as liver or kidney damage, cancer, or chronic lung disease;
- corrosive chemicals burn the skin, eyes, or respiratory tract;
- irritants can inflame the skin or lungs, causing conditions such as dermatitis or bronchitis;
- sensitizers may exert long-term effects, especially to the skin (such as contact dermatitis) and to the respiratory tract (such as occupational asthma) by inducing an allergic reaction; and
- explosive or flammable substances pose immediate danger of fire and explosion, causing damage to the body through direct burning, or through inhalation of toxic fumes emitted during combustion.

Safety Data Sheets (SDS), also known as Material Safety Data Sheets (MSDS), are designed to provide relevant information regarding the identity, physical characteristics, safe storage, use, disposal, first-aid treatment, and spill management of substances that are handled in the workplace. The information includes whether the substance is deemed to be a hazardous and/or a dangerous goods item. At a minimum, the SDS should be consulted before the first use of a chemical or other substance within a laboratory, or if practitioners are unfamiliar with the product. Copies of SDS should be retained according to legislative requirements. In some jurisdictions, electronic SDS management systems can allow an efficient way of accessing up-to-date SDS information.

Sharps

Sharps are objects that have sharp edges or points that have the potential to cut, scratch, or puncture the skin. Sharps can cause physical injury and have the potential to introduce infectious and toxic agents through the wounds created in the skin. Examples include hypodermic syringes and needles, knives, or broken glassware.

All forensic practitioners have a responsibility to handle and package sharps safely. Particular care should be given to ensuring that sharps are appropriately labeled when packaged. Sharps such as knives could, for example, be packaged in clear plastic tubes, making it easier for a person opening the item to identify the contents and the direction the sharp items is facing. Forensic Labs should be encouraged to develop policies that encourage forensic practitioners and others that submit items to develop safe-packaging procedures.

Biological Material

Examples of 'biological material' commonly encountered in forensic examinations include body tissue, blood, and body fluids (urine, saliva, vomit, pus, seminal fluid, vaginal fluid, and feces). Biological material is potentially hazardous as it may contain infectious agents such as viruses, bacteria, fungi, and parasites that cause a variety of communicable diseases.

Hair, fur, and items of clothing that have been in close contact with humans or animals may also harbor parasites such as fleas or nits.

When examining plant material such as cannabis, consideration should be given to the presence of *Aspergillus* sp. mould. If the *Aspergillus* spores are inhaled into the lungs, a serious, chronic respiratory or sinus infection can result. If mould is visible, the cannabis should be treated as a biological and respiratory hazard.

It is impossible to determine the prevalence of infectious or communicable diseases in the environment in which forensic practitioners work. Consequently, practitioners should adhere to recommended procedures for handling biological material and adopt an approach known as the 'standard precautions'. This approach requires practitioners to assume that all biological material is a potential source of infection, independent of diagnosis or perceived level of underlying risk.

Vaccinations should be offered for practitioners. The types of vaccinations given may depend on whether work is confined to the laboratory or whether work is performed in the field, as well as whether forensic practitioners are likely to be deployed overseas where other diseases may be more prevalent.

Firearms

Forensic practitioners may retrieve firearms from crime scenes. All personnel who may be required to handle firearms, either in the field, in the laboratory, or in support roles such as property or exhibit stores should be trained in how to render a firearm safe. As with the 'standard precautions', it is important to consider all firearms as potentially loaded, and adopt the practice of never pointing a firearm in the direction of another person, even after it has been rendered safe.

Firearms examiners, who undertake firearms investigations including test firing and bullet recovery, will be exposed to hazards such as noise and lead. They should have their hearing and blood lead levels monitored on a regular basis, to ensure that hearing protection is being worn and is functioning correctly, and any exposure to lead from the firearms is quickly identified and addressed.

Computer Forensics Laboratory

Computer forensic examiners specialize in obtaining, analyzing, and reporting on electronic evidence stored on computers and other electronic devices. Crimes involving a computer can range across the spectrum of criminal activity, from child pornography to theft of personal data to destruction of intellectual property. Potential hazards involve static postures, occupational overuse, and stress from viewing graphic images.

Some suggestions to minimize the stress from viewing graphic images are as follows:

- psychological assessment before and after viewing graphic material, and periodically;
- exposure to only one medium, for example, visual material only, rather than examining both sound and visual material simultaneously;
- specifying limits as to the amount of time spent examining explicit material in a day, and

- ceasing any examination of explicit material the end of their shift, to allow themselves time to refocus attention away from this stressor.

Electrical/Machinery

Forensic laboratories use a wide range of electrical equipment and machinery. Practitioners need to ensure that any inherent risk from electric shock is mitigated. The use of residual current devices (safety switches) is an appropriate strategy, as is visual inspection and periodic testing and tagging of power cords, to detect obvious damage, wear and other conditions which might render it unsafe by a person qualified to do so under the legislation in effect in the jurisdiction.

Fume Cupboards

Fume cupboards are integral to minimizing the risk of exposure to chemical and biological hazards. Not all fume cupboards are suitable for all hazards. Fume cupboards should be maintained and inspected periodically. During maintenance, attention should be given to:

- The fume cupboard itself, including flow rates and replacement of absorbents or filters.
- In the case of externally vented fume cupboards, the ductwork and location of external vents. This is particularly important during any building maintenance or refurbishment.

Fume cupboards must be used for all operations that have the potential to release hazardous fumes, mists, or dusts.

- Before commencement of work, ensure that the fume cupboard is clean and free from contamination.
- Ensure the minimum of equipment is stored in the fume cupboard and is placed toward the back of the cupboard to reduce disturbance to the air flowing into the fume cupboard.
- Lower the sash as far as practicable during use to improve fume containment.

Recirculating fume cabinets rely on filtration or absorption to remove airborne contaminants released in the fume cabinet before the exhaust air is discharged back into the laboratory. They are suitable for light to moderate use with a known range of substances. The range of substances for which each cabinet can be used is limited by the need for compatibility with the chemicals in use as well as with the particular type of absorbent or filter fitted to the cabinet.

Robotics

The introduction of automated robotic platforms has significantly enhanced the efficiency of forensic analysis. The use of robotics is becoming more common and is very useful for a range of repetitive laboratory tasks. Besides saving time, robotics overcomes the need for repetitive work involved in pipetting, eliminating musculo-skeletal injuries.

Hazards associated with robotics include the risk of exposure to the chemicals used in the work, electrocution, and cutting, stabbing, or shearing from the moveable parts of the robot. The interlocks on the robots should not be bypassed.

X-rays

X-rays are used in analytical and imaging instrumentation. Potential exposure to x-rays is generally localized to specific parts of the body, usually the hands or fingers. Depending on the x-ray energies delivered, effects may range from erythema (redness) at point of exposure, blood changes, cancer through to death. Depending on the legislative requirement in each country, practitioners working with x-ray equipment may be required to use dosimeters to assess radiation dose.

Lasers

Lasers span the visible and nonvisible electromagnetic spectrum and have many applications in forensic science, including Raman spectroscopy. Lasers are generally classified according to the level of risk they represent. Damage from laser beams can be thermal or photochemical. The primary sites of damage are the eyes and skin. Hazards associated with laser work may include:

- fire,
- explosion,
- electrocution, and
- inhalation of contaminants from laser interactions.

Precautions for use of lasers include:

- Display the class of laser in use.
- Appropriate protective eye wear with side protection and appropriate attenuation for the wavelength(s) in use must be worn.
- Interlocks on the laser should not be bypassed.
- Keep the laser beam path away from eye level whether one is seated or standing.

High-Intensity Light Sources

High-intensity light sources such as the Polilight® provide a range of colored light bands and white light for forensic work.

- Care should be taken that high-intensity white light is not directed onto any object at short distances from the end of the light guide, as this can cause severe heat damage to the object, and may result in a fire.
- The light beam should never be directed at eyes as the light can cause permanent damage.

Manual Handling

Manual handling refers to any activity that involves lifting, lowering, carrying, pushing, pulling, holding, restraining, or the application of force. Only a very small number of manual handling injuries are caused by the lifting of heavy weights alone. Actions such as reaching, twisting, bending, or maintaining static postures contribute to injury affecting the muscle or skeletal systems of the body. These musculo-skeletal injuries predominantly involve the neck, back or shoulder or arm muscle, tendon, ligament, or joints.

Injuries may be caused from activities such as maintaining static postures while working at fume cupboards, repetitive

keyboard and mouse work, pipetting, prolonged use of comparison microscopes.

Some preventative strategies include:

- Seeking further assistance to have the activities assessed to minimize the manual handling risks inherent in the activity.
- Planning tasks so that rest breaks are scheduled.
- Choosing the best tools for the tasks.
- Alternate hands while using a mouse, if possible.

There is a move to make instruments smaller and more portable for use at crime scenes. While this has significant benefits, including potentially reducing the number of exhibits collected, moving equipment can also raise manual handling concerns.

General Laboratory Management

Housekeeping is important in laboratories. It is important to maintain clear passageways, have proper labeling of chemicals, clean and uncluttered work areas and appropriate storage. The handling of powders is a potentially hazardous operation and good housekeeping can help minimize airborne contamination from spilled materials. Having a planned preventative maintenance program and regular inspections of the workplace, plant, and equipment are essential for the smooth running of the laboratory.

Handling of Exhibits in Court

Each evidential item must be appropriately packaged and sealed, if this is not already the case, before it is exhibited in court. Items such as clothing which are normally stored in paper may need to be repackaged in clear plastic allowing the item to remain sealed, and minimizing the risk of cross contamination when handled in court. Caution should be exercised against opening exhibits in court, in case any hazards such as mold or irritant fumes are released.

Hazards in the Field

Forensic practitioners are often required to work or train in the field. Consideration should be given to managing hazards which may affect practitioners, including:

- environmental hazards such as heat, cold, humidity or wet weather, the terrain, and fauna or flora at the scene;
- the type of operation, for example, working in a clandestine laboratory often involves quite specific hazards;
- the possible presence of offenders or other security risks such as booby traps at a scene; and
- the availability of first aid and emergency response domestically and overseas.

The risks from these hazards should be considered within the scope of the exercise or operation. Some possible responses to hazards, which may be considered in a dynamic risk assessment, include:

- Designating a location for emergency equipment, such as a crime scene vehicle, and ensuring that disinfectants, antiseptics, and a first aid kit are easily accessible;
- Planning an emergency exit from the scene and ensuring that this is communicated to all personnel present;
- Establishing a decontamination point if there is exposure to chemical or biological material;
- The use of appropriate PPE including sunglasses, sunscreen, and hats when working outdoors;
- Depending on the external temperature, work activity, duration, and PPE worn, practitioners should have access to shade for rest and adequate fluids if required during hot weather to prevent heat stress. The wearing of PPE including chemical suits and respirators requires longer and more frequent periods of rest break for recovery in hot temperatures and humid environment;
- In cold weather, provision should be made to have adequate warm clothing and a sheltered area;
- The risk of animal or dog bites while attending a crime scene should not be discounted. If practitioners are searching in vegetated areas, the risk of snake or tick bites should be considered, along with possible exposure to plants such as poison ivy or stinging nettles.

Confined Spaces

Forensic practitioners may have to enter confined spaces. Due to the high risks associated with entering the confined space, many jurisdictions mandate that entry into a confined space must not be made until a confined-space permit has been issued. Practitioners must receive specific training before work or entry into confined spaces.

Chemical Biological and Radiological and Nuclear Incidents

Forensic practitioners may be required to attend a chemical biological and radiological and nuclear (CBRN) incident. CBRN incidents where forensic practitioners may attend and conduct examinations include:

- chemical (warfare agent, toxic industrial chemical);
- biological (weaponized agent, natural disease);
- radiological (discrete, or wide area contamination); and
- nuclear.

Depending on the response agency protocol in place, forensic practitioners may be working closely with the Fire Brigade and other emergency first responders. Entry must not be made into the 'warm' or 'hot' zone of the scene without consultation with the other emergency first responders.

Clan Labs

Clan labs pose a significant threat to the health and safety of police officers, forensic practitioners, the general public, and the environment. There are many hazards associated with clan labs including:

- flammable materials and/or explosive atmosphere;
- acutely toxic atmospheres;
- leaking or damaged compressed gas cylinders; and

- traps and hazards deliberately set to cause injury or death to police and other responders.

As a result of the frequency at which clan labs are encountered and the severe and variable risks associated with the investigation, many jurisdictions have developed specific policies and procedures concerning clan lab investigations.

For forensic practitioners to deal with clan labs requires a high level of fitness as well as technical expertise. Practitioners have to understand:

- illicit drug chemistry;
- how to neutralize the risks of explosions, fires, chemical burns, and toxic fumes;
- how to handle, store, and dispose of hazardous materials; and
- how to treat medical conditions caused by exposure.

Practitioners must also wear full protective equipment including respirators and may be required to move equipment at the clan lab in the process of collecting evidence. The storage and handling of unknown chemicals from clandestine laboratories or seizures should also be considered. Preliminary identification should take place, before its storage or disposal.

When unknowns such as 'white powders,' chemicals (in liquid, solid, or gas state) or biological materials are encountered in the field, it is prudent to be cautious and obtain up-to-date intelligence to shed more light on what is at the scene. It may be an explosive material or contain anthrax spores or ricin or something as innocuous as talc.

Some precautions include:

- wearing the appropriate level of protective clothing/equipment for the activity;
- avoiding direct contact with the substance, even if only in small quantities;
- not smelling or tasting anything from the scene;
- noting physical characteristics such as color, form, and consistency;
- where it is safe to do so, looking for hazard symbols on packaging or labels if available; and
- seeking specialist advice if unable to identify the substance.

Potential Hazards during an Overseas Deployment

Forensic practitioners can be required to work overseas to assist with large scale disasters. An example was the Thailand Tsunami Victim Identification process involving forensic practitioners from 30 countries working to recover and identify bodies. Forensic practitioners need to be mindful of hazards likely to be encountered during an overseas deployment depending on the location, magnitude of the operation, and how many practitioners are deployed. Some hazards to be considered include:

- climatic demands;
- remote and sometimes dangerous terrain;
- different cultural sensitivities;
- security requirements;
- different levels of infrastructure support at the locality;
- logistics, including the transport of large quantities of equipment, manual handling, setting up, and packing up;
- different hygiene levels;

- diseases that can be transmitted by insect and or animal vectors;
- the possibility of infectious diseases; and
- asbestos and other hazards in buildings.

Work-Related Stress

Practitioners at work may experience work-related stress. There are some specific stressors unique within forensic work. Forensic practitioners may experience workplace-related stress due to their attendances at morgues, violent crime scenes, Disaster Victim Identification or from requirements to view explicit or graphic material or images.

Indicators of stress include changes in eating habits, tiredness due to changes in sleep patterns, frequent absences from work, reduced productivity, concentration, motivation, and morale. Physical symptoms may include headaches, abdominal pains, diarrhea, constipation, high blood pressure, insomnia, anxiety state, and depression.

Many organizations offer programs to provide assistance to employees, including counseling to help practitioners to deal with work-related stress or resilience training to manage work-life balance.

Sequential Unmasking: Minimizing Observer Effects in Forensic Science

Glossary

Blind testing Blind testing is a method of testing in which an examiner records the results of any test or procedure without knowing the identity of the samples or what result might be expected. In forensic science most blind testing is done in a situation where the examiner knows he is being tested, but does not know what the answer is or should be. Double-blind testing is a procedure in which neither the analyst performing the testing nor the persons administering or assigning the testing (case) know the expected results of the examination. A double-blind procedure is used to guard against both confirmation bias and observer effects.

Confirmation bias The tendency to test a hypothesis by looking for instances that confirm it rather than by searching for potentially falsifying instances. In a less scientific setting, the tendency to seek and interpret information that confirms existing beliefs.

Context effects The influence of environmental factors on one's perception of a stimulus using top-down cognitive processing of sensory information to construct a completed perception of the observation or phenomenon.

Domain-relevant The domain of a model that necessitates a restriction on the values that can be used in the task at hand.

In forensic science, this comprises only that information necessary and sufficient (domain-relevant) for an analysis, comparison, or interpretation of an item or items of evidence. It is information without which the most basic physical evidence examination, analysis, and comparison cannot be correctly accomplished.

Observer bias Errors that occur when the observers (or researcher team) know the goals of the study or the hypotheses and allow this knowledge to influence their observations during the study. Error is introduced into measurement and judgement when observers overemphasize results that they expect to find and fail to notice results that they do not expect.

Observer effects The tendency for the desires and expectations that a person possesses to influence her perception and interpretation of what she observes. In other words, the results of an observation depend upon the state of the observer as well as the thing observed.

Sequential unmasking A process of testing whereby relevant information about the evidence is revealed (unmasked) in an orderly fashion, providing the appropriate level of domain-relevant information necessary and sufficient to perform an analysis, comparison, or interpretation on a piece of physical evidence.

The Concept of Sequential Unmasking

In 2008, a letter to the editor of *Journal of Forensic Science*, entitled Sequential Unmasking: A Means of Minimizing Observer Effects in Forensic DNA Interpretation, was published. Although this certainly was not the first time the concept of blinding a forensic examiner to extraneous information had been suggested, it was the first publication in the knowledge of the authors that included forensic practitioners among the authors. Other disciplines represented among the diverse group included law, psychology, economics, and statistics.

The initiative used forensic DNA typing as a model system, in part because both the existing procedures, as well as the data itself, are relatively well defined. The main contribution of the piece was to reimagine conventional blind testing in a way that would be more pertinent to the way forensic science is practiced. Hence the authors proffered the term 'sequential unmasking' to highlight the idea that forensic scientists would receive all relevant information in an orderly fashion. The idea was to minimize the opportunities for inadvertent bias, while still providing the examiner with all the information needed for a complete and relevant analysis.

Several key points attempted to address the practical implementation of sequential unmasking procedures. In addition to the idea of sequentially unmasking of (rather than withholding)

information, the authors suggested using a case manager (not a new idea in and of itself) to manage the flow of information. Another concept discussed was the idea of domain-relevant and domain-irrelevant information. The abbreviated nature of a letter to the editor did not allow for expansion of this idea, and it will be explored further in this article. Finally, the authors proposed that, although it undoubtedly would be more challenging, sequential unmasking procedures should certainly be applied to forensic disciplines other than DNA.

The Foundational Basis for Cognitive Effects

The previous edition of this Encyclopedia included an article by William C. Thompson on observer effects, context effects, and confirmation bias in forensic science. So as not to be repetitive, the reader is referred to that article for more extensive background information that is only briefly summarized here. An extensive list of references is also provided at the end of this article.

Although many different terms are used to describe different aspects of effects that may induce cognitive bias, the reader is cautioned to avoid being distracted by the different terms of art such as observer effects, context effects, confirmation bias; the important point is that no human being, and forensic

practitioners are human beings, operates in a vacuum. Human beings live in the real world and are constantly bombarded by external stimuli. The way in which humans process those stimuli allows them to function at a high level. However, the filters (schemata in the language of psychology) that higher brain functions use to organize information prioritize and emphasize some information over other information. While this is useful and necessary for survival, it can affect, indeed bias, the way we make decisions. Judgment and decision making lie at the heart of interpreting forensic data.

The underlying idea of context and observer effects derives from a rich and well-documented cognitive psychology literature. Certainly, the idea that human beings do not always recognize all of the factors that influence their judgments and decisions is widely accepted in the field of psychology. Additionally, an extensive knowledge base documenting the existence of cognitive effects exists in the history of science itself, as well as current systematic empirical studies, and syntheses and meta-analyses of experimental data, and case reports. It is simply impossible to disassociate the inherent characteristics of an object or event from the state of the observer and the context in which the observation takes place; the very act of human observation alters the ultimate perception. The tendency of observers to perceive and interpret data in a manner consistent with their preconceptions is exhibited most strongly in the face of ambiguous data, and either strong emotions or clear expectations.

Cognitive Effects Occur at a Subconscious Level

It is worthwhile emphasizing two key concepts that seem to be perpetually misunderstood. First, the type of potential bias exerted by context, observer, and other related effects occurs without humans being aware of it; it works at a level that cannot be accessed by the conscious mind. Therefore, no matter how well meaning, well educated, and well trained the analyst, she is incapable of simply willing away such influences; expertise does not insulate one from the influence of expectation and situation. This means that the most effective way to minimize opportunities for potential bias is procedural.

Susceptibility to Cognitive Effects is Not a Flaw

Second, susceptibility to context effects is not a weakness or failing in the expert; it derives from the way the human brain processes and organizes information, a capability essential to the functioning and survival of humans in the natural world. However, in the situations previously described, including the examination of physical evidence in a forensic context, it can work against individuals.

The Most Effective Antidote to Cognitive Effects is Procedural

In order to combat the potential biasing effects inherent in the observer and ubiquitous in context, blind testing protocols have become standard operating procedure in many scientific disciplines, including clinical 'evidence-based' medicine, research science, and other applied sciences; the idea is culturally embedded to the point that it is simply taken for granted as 'good practice'. It is even exemplified in scholarly publications

as the well-known anonymous peer-review process. Blind and double-blind testing protocols further pervade such diverse arenas as consumer product testing, music auditions, and grading student exams.

Support for Blind Testing in Forensic Science

Given that physical evidence items associated with crime events can, by their very nature, present extremely ambiguous data, and that, unquestionably, the criminal arena, and even the civil arena, represent some of the most emotionally heightened contexts imaginable, the forensic examination of physical evidence provides a strong confluence of factors provoking cognitive effects. Additionally, subjective judgment by the human observer pervades the interpretation of forensic evidence. Although no discipline is immune, including DNA typing, it is pattern evidence (e.g., fingerprints, shoe prints, tool marks, and firearms) that appears most vulnerable to biasing influences. The random pattern nature of this type of evidence is both strength and weakness. The randomness of the patterns generates the diversity; however, that same characteristic also creates challenges in defining objective interpretation criteria. Additionally, as currently practiced, the comparisons rely almost entirely on human judgment to form conclusions about whether a particular evidence item could derive from a specific source. Lest the reader infer that DNA and other types of instrumental evidence are immune to observer effects, it is important to point out that any physical evidence loses clarity and gains ambiguity as it increases in complexity and decreases in quantity and quality. Interestingly, while research has been performed to investigate the consequence of context effects on fingerprints, proposals to investigate whether the same phenomenon occurs with ambiguous DNA profiles have been dismissed as unnecessary research (personal knowledge, authors).

Nevertheless, no one, not even the most vocal critics, has suggested that most, or even many, conclusions derived from the comparison of pattern evidence are patently erroneous due to the subtle influence of observer effects. However, psychology predicts and a growing body of research confirms that in a demonstrable number of cases in which ambiguous evidence is analyzed by an examiner who is presented with information that is unnecessary to perform the initial comparison, his conclusion may change substantively and directionally with the extraneous information. Sufficient evidence exists, both from research and from casework examples, that the potential for observer bias can no longer be refuted or ignored.

Psychological and social studies of science inform us that context information, such as expectations about what one is supposed to see or conclude, has been found to exert a small but relentless impact on human perception, judgment, and decision making. Given the potentially momentous consequences of an erroneous conclusion made in the forensic setting, it seems surprising to many observers that safeguards to minimize the chance of analyst bias are not instituted as a matter of course. Even if a frank error resulting from one of several types of cognitive bias occurs only rarely, is not the cost (whether monetary or in human resources) worth the potential benefit (life or liberty of a human being)? And if the cost is relatively small, would it not be easier for forensic scientists to

be able preemptively to dismiss any accusation of possible bias affecting their examination? In the next section, some of the objections voiced from within the forensic community to implementing sequential unmasking protocols are discussed.

Arguments Against Blind Testing in Forensic Science

Although isolated pockets of support exist, the forensic science profession as a whole has yet to embrace the idea of instituting infrastructural and procedural solutions that minimize the opportunity for analyst bias. Although the profession appears to be slowly accepting the idea that potential for inadvertent bias exists, there remains a general resistance to embrace procedural solutions to minimize the opportunity for context and observer effects. Why is this?

Perhaps because forensic scientists operate in an adversarial situation imposed by the legal system, they tend to be sensitive to perceived accusations implying a lack of integrity. Some, whether through mis-hearing or misunderstanding, confuse observer effects with deliberate fraud or base incompetence. They point to the fact that examples of patent fraud are relatively rare (true, but irrelevant) and that competence should be addressed through training and education (also true, and also irrelevant). Although some instances of these other problems may be detected using procedures to minimize bias, the directed goal of sequential unmasking is to address the unintentional and unintended influences of observer and context effects on forensic examinations. They should be welcomed as protective measures to insulate the expert from both the actuality and the perception of bias.

Another argument is that the potential cost in both monetary and human resources to institute sequential unmasking protocols outweighs the benefit of reducing the relatively small number of frank errors resulting from observer effects. Some argue that it would be very difficult to make the changes in an institutionalized system, and that efficiency would be so severely affected as to render implementation of sequential unmasking procedures unworkable. Certainly, some of this depends on the extent of the changes, as well as how they are implemented. Supporters argue that relatively simple measures can be put in place immediately, and more complex institutional changes could be introduced over time. One way to actually measure impact and efficiency might be first to implement variations of sequential unmasking procedures on a limited basis, perhaps using a model system. This would be particularly useful for disciplines in which the information flow is less obvious than for forensic DNA typing. On the other hand, several laboratories are known which have already implemented at least first level type sequential unmasking procedures (analyzing and documenting evidence items before comparison with reference items) in their DNA sections virtually seamlessly.

Yet another objection to implement sequential unmasking procedures via a case-manager approach decries a waste of expertise among laboratory personnel. Those who make this argument have apparently misunderstood the intention of a case-manager system in the context of sequential unmasking. The case manager would be a high-level scientist within the laboratory (not a law enforcement officer external to the

laboratory, as has been suggested by at least one critic), and no reason exists why the duty should not rotate among qualified examiners. The assumption of a static case-manager role that would relegate all other analysts in the laboratory to mere technicians is an artificial and insubstantial roadblock. Said another way, it is the proverbial straw man.

A more substantial complaint about sequential unmasking is that it would somehow deprive the examiner of information required to competently and fully interpret forensic evidence in the context of the case. Again, the fear appears to embody the image of a laboratory full of mere technicians, supervised by detectives and attorneys, who would direct the flow of information and interpret the evidence in the context of the case. This could not be further from the intention of the architects of sequential unmasking. Assuming the forensic scientist has received the appropriate education and training, and acquired some reasonable amount of experience, that expert can and should assist the justice system in understanding the evidence in the context of the case; in fact it would be incompetent and irresponsible not to provide this expertise. However, it is not necessary for the practitioner to receive all the information at the beginning of the examination to accomplish this goal. The examiner can be protected from context and observer effects by sequentially revealing information to her in a sequential fashion, on an as-needed basis. This might begin with the minimal information required to properly and adequately sample and analyze a piece of evidence. At each subsequent step of analysis and interpretation, additional information required to proceed would be revealed. At the end of any particular procedure, the analyst would be privy to all domain-relevant information; when the technical analysis has been completed and documented, information that might only be questionably domain-relevant can be unveiled as well. This allows for the documentation of results in an orderly fashion, including any modifications resulting from the new information. This will generate a complete record of how conclusions may have been updated with the acquisition of new knowledge about the case.

Some have acknowledged that the potential for cognitive bias exists, but that those concerns are completely addressed by quality assurance measures already in place. Specifically they offer that 'peer review' and 'blind verification' offer protection equivalent to or better than sequential unmasking procedures. First, the term 'peer review' properly applies to a specific process through which a manuscript submitted for publication in a professional journal is anonymously reviewed by several individuals in the same field to determine its suitability for publication. Co-opting this term as a synonym for the internal technical review performed in a forensic laboratory is inappropriate and misleading. It implies greater weight and authority to an internal technical review than is merited, conferring upon it a false sense of autonomy and independence.

Use of the term 'verification' to describe an independent examination of an item or data is also problematic. The term strongly implies that the conclusion of the primary analyst will in fact be verified, and would seem to leave little room for refutation. As thought follows language, it has been suggested that more neutral terms, such as independent examination, analysis or interpretation, are more appropriate than verification. Most importantly though, there is no knowledge of any

published data that indicate that the implementation of these types of quality assurance measures, as used by forensic laboratories today, minimizes observer bias. These procedures, while useful and necessary for other reasons, do not substitute for sequential unmasking.

One highly debated parallel is the experience of clinical medicine, in particular radiology. Some advocates of blinding procedures in forensic science point to the interpretation of body scans as an analogy for interpreting forensic evidence. They offer that radiologic films are always interpreted by technicians who are expert in reading the data, but who are never provided with information about other symptoms. The physician, then, is the expert who puts the blind conclusion of the radiologist into context with the rest of the symptoms, and diagnoses the disease. Many in the forensic community are offended by this analogy, arguing that (1) the forensic practitioner is more analogous to the physician than to the radiologic technician and (2) many radiologists are provided with patient histories, and in fact are not blinded to extraneous information. A paucity of information, published or otherwise, makes it difficult to determine whether strong support exists for either point of view.

Finally, critics have complained that advocates of sequential unmasking intend that it should be imposed only upon prosecution laboratories, while independent experts working mostly for the defense remain privy to all case information from the beginning of their review. While implementation is certainly more challenging in the private sector for a variety of reasons, independent experts should not be immune from implementing sequential unmasking procedures. The most critical aspect, that of analyzing evidence items, as well as documenting the characteristics of the evidence before comparison to any reference items, can be readily accomplished even by the sole practitioner. Any laboratory, government or independent, would require additional infrastructure to completely implement sequential unmasking protocols.

Sequential Unmasking in Forensic Science

Because so many forensic practitioners interpret blind testing procedures to mean that they will be forever and enduringly blind to any and all case information, and will be restricted to performing a simple technician type comparison as an end-point, it is important to clarify the basic sequential unmasking protocol. Both descriptors, sequential and unmasking, are meaningful and critical. Together, they describe a linear flow of information, beginning with only the most essential pieces, and then in an orderly step-wise fashion, revealing additional information that may expand to include the entire case circumstance, if appropriate. The idea is that observations, results, and conclusions will be documented at each step. The practitioner is not locked into any particular statement made at some point in the analysis; rather, if her conclusions change, the reasoning supporting that change is documented such that it may be subject to future review. While, at first, this may seem restrictive, even burdensome, such a step-wise procedure not only minimizes opportunities for potentially biasing context and observer effects but also protects the analyst from gratuitous accusations of bias. If the analyst has documented the initial

characterization of the evidence, and the subsequent comparison, she may then properly consider additional information, and eventually, interpret the evidence in the context of the case, secure in the knowledge that she has protected herself from undue influences during the initial evaluation, examination, analysis, and comparison. Such a process patently precludes any notion that the analyst would ultimately lack information relevant to a complete and informed conclusion.

The responsible forensic professional not only may, but must, eventually consider the evidence in the context of the case. Both the initial blinding and the subsequent revelation are critical to the competent practice of forensic science. Interpreting the evidence in context with other physical evidence analyses, case facts, or other information should not be left to law enforcement or legal players, who may lack critical expertise in the examination or interpretation of physical evidence. In the perennial words of Robert Rosenthal, the practitioner should be kept 'as blind as possible for as long as possible'. The requisite addition to that statement is that the practitioner should receive information in an orderly, documented fashion so as to fully assist the judicial system in understanding the import of the physical evidence.

Domain-Relevant (and Domain-Irrelevant) Information

The idea of domain-relevant (and conversely domain-irrelevant) information may have been introduced in the seminal paper by Saks et al. It is a fundamental concept in applying sequential unmasking and is mentioned in the JFS letter, but because it has not been subject to subsequent discussion or expansion, the concept has remained unnecessarily mysterious. Consequently, a fair amount of consternation has ensued about this concept. This concern is exacerbated by the fact that no detailed discussion has followed, nor has any guidance been provided as to how to incorporate it into an evidence examination protocol.

The idea of domain relevance is probably better defined dynamically rather than statically. In other words, although examples and general guidelines can be proffered, determining the relevancy of various pieces of information on a case-by-case basis is, in fact, one of the roles of the case manager. In a larger sense, determining what information is necessary and sufficient (domain-relevant) for a technical comparison, and at what stage it should be provided is likely a discipline-specific exercise. It cannot and should not be imposed from above or from outside the discipline. That would be a recipe for disaster. Only those intimately involved in the examination and analysis of a particular type of evidence know what information is intrinsic and essential to an initial analysis or comparison, and which information can be revealed at later stages in the process to optimize the sequential unmasking procedure for the best analysis with the least opportunity for bias.

Generally, domain-relevant information can be understood as that without which the most basic physical evidence examination, analysis, and comparison cannot be accomplished. The primary items obviously include the evidence sample and, after the evidence examination is complete and fully documented, the reference or exemplar sample. However, the comparison of the two might require additional information

that is not intrinsic to the items being compared. For example, the presence of a scale is required for both the evidence and exemplar prints in a shoeprint comparison; otherwise an insufficient basis exists on which to base a comparison. In DNA analysis, information that the evidence derives from an intimate sample would be revealed early in the process so that the analyst could proceed with mixture deconvolution, but only after the evidence sample was analyzed and a commitment made (in the form of documentation) to the types present. It would certainly be appropriate to reveal the profile of the intimate reference source so as to deconvolve a mixture before comparison with a suspect reference sample. Some examiners have argued that knowledge about the substrate on which a fingerprint was deposited is critical domain-relevant information required for a competent analysis; other observers, however, have argued that the pattern inherent in the print can and should be interpreted first absent this knowledge, or even that this information would and should not change determination of characteristics in the evidence print. Another point of current discussion in the fingerprint community is when an examiner should be informed that a set of exemplars is the result of an AFIS database search.

One might ask whether an examiner should consider the results of a related analysis from another discipline in the interpretation of his results. For example, assume that a usable fingerprint is located on a gun, and a small portion of the ridge detail is also tested for DNA. Assume that they implicate different individuals. One would not want to take the chance that either analyst would be influenced by the conclusions of the other, especially if the evidence is ambiguous. However, clearly, someone eventually has to think about an explanation for the apparently discrepant results. Was there an error in collection or analysis? Was another fluid present on the weapon underneath the fingerprint? Was an adjacent area sampled that would inform the examiner about background material? Does another possible case-related explanation exist that could reconcile the results? Again, this is the value of the case manager. But ultimately, after each discipline-specific examiner has completed his analysis, and documented his results and conclusions, no reason exists to withhold this information, or not to solicit his input as to explanations for the apparent discrepancy. The solution lies in the orderly sequence of unmasking information, and careful and complete documentation of data, interpretations and conclusions at each step.

Finally, examples of information that are clearly domain irrelevant are considered. For example, the physical evidence examiner does not need to know that the suspect has a rap sheet 12 miles long, or that he has confessed to the crime, or that eyewitness reports place him at the scene. He does not need to know that this is a high-profile case commanding media attention. Yet this type of information is regularly included in sensational fashion on requests for evidence examination. A generalization of such a request is to name the suspect as the factual perpetrator of the crime, and to emphasize that positive results are required to arrest and charge a suspect, or to apprehend him because he is a flight risk. Every examiner has seen specific variations of this transmittal. While the back story certainly serves to put a human face on what might otherwise be a mundane, even boring, occupation, providing this information up front jeopardizes the objective

analysis that can, in the end, provide the most reliable and useful results to the judicial system. No one is suggesting that the analyst never learn the case story; in fact by the conclusion of a case, often after a conversation with the detective, and certainly if a case proceeds to trial, the examiner will be fully informed, fully aware, perhaps even immersed, in the case details. However, if the order of information revelation is controlled, both the practitioner and the analysis are protected and the information offered to the criminal justice system is more secure.

It is neither an easy nor a trivial exercise to formulate standards for domain-relevant information or to determine a dividing point between that and domain-irrelevant information. Nevertheless, such difficulties do not justify the complete absence of standards of practice that now exist. A useful and practical plan would be for the various disciplines that comprise forensic science to meet and begin discussing this matter. The forensic community would do well to take ownership of this issue before it is imposed upon them from the outside.

Exemplar Line-Ups

A procedure that is different from conventional blind testing, and which could be very useful to incorporate into a sequential unmasking protocol, is exemplar line-ups. This procedure has in the past been referred to as 'evidence line-ups'. This is a misnomer, hence confusing. The line-up consists of several known reference samples that might be considered as the source of the evidence; no additional evidence samples are introduced.

Everyone is familiar with photo line-ups presented to eyewitnesses. It is standard practice for the photo pack to be presented as a line-up (a group of images at the same time), and officers are instructed to avoid either verbal or physical cues to the eyewitness that might prejudice them toward a particular photo. How well this is accomplished in practice can be debated, but the intent is correct.

A physical evidence line-up would proceed in similar fashion. For example, the fingerprint examiner would receive a group of ten-print exemplars, one of which is from the suspect; the others would be prints exhibiting similar patterns, but unrelated to the crime event. In this way, the examiner avoids the inherent bias that the suspect is the source of the evidence print simply because his ten-print card was submitted as the only exemplar for comparison to the evidence print. This procedure is readily extended to just about any discipline in which comparisons are required to determine source. Certainly, detractors will argue that the extra time and work to perform multiple comparisons is not worth the cost in human and monetary resources to achieve the potential benefit. These questions could be addressed by simple experiments using model systems.

Conclusion

While the existence of cognitive effects leading to observer bias is well documented in the cognitive psychology literature, and the idea of blind testing is widely accepted across various

scientific and medical disciplines, these ideas have historically been dismissed by the forensic profession. Although the potential for bias is beginning to be more widely accepted by forensic practitioners, resistance to procedural solutions remains significant. The reader is referred to the extensive bibliography offered below for additional information and education on these current and critical issues.

Glossary

Capillary electrophoresis Electrophoresis in a circular tube with an internal diameter less than 100 μm .

Electroosmotic flow (EOF) Flow of solvent through movement of ions held near a charged surface in an electric field.

Electrophoresis Movement of ions in an electric field.

Electrophoretic mobility Constant that defines the speed and direction of movement of ion.

Joule heating Heat generated from movement of ions in an electric field during electrophoresis.

Microchip electrophoresis Electrophoresis in a micrometer channel sealed in a flat planar substrate.

Abbreviations

BGE	Background electrolyte
C	Concentration of the component in the sample solution
CE	Capillary electrophoresis
D_m	Diffusion coefficient of the analyte
DNA	Deoxyribonucleic acid
E	Applied electric field
ϵ	Dielectric constant of the medium
EC	Electrochromatography
ECD	Electrochemical detection
ESI	Electrospray ionization

EKC	Electrophoretic chromatography
EOF	Electroosmotic flow
FASS	Field-amplified sample stacking
GC	Gas chromatography
HPLC	High performance liquid chromatography
H_{th}	Height equivalent to the theoretical plates
IEF	Isoelectric focusing
ITP	Isotachopheresis
L_d	Capillary length from injection to detector
LIF	Laser-induced fluorescence
L_{tot}	Total capillary length
MALDI	Matrix-assisted laser desorption/ionization

μ_{app}	Apparent mobility	η	Solution viscosity
MEEKC	Microemulsion electrokinetic chromatography	SDS-PAGE	Sodium dodecyl sulfate-polyacrylamide gel electrophoresis
MEKC	Micellar electrokinetic chromatography	SE	Sieving electrophoresis
μ_{EOF}	Electroosmotic mobility	SiO^-	Silanoate group
μ_{ep}	Electrophoretic mobility	SiOH	Silanol group
MS	Mass spectrometric	t	Migration time
μTAS	Micro-total analysis system	t_{inj}	Injection time
m/z	Mass-to-charge ratio	UV	Ultra-violet
N	Number of theoretical plates	V	Applied voltage
OHP	Outer Helmholtz plane	v_i	Velocity of an ion
Δp	Pressure difference	v_{inj}	Injection volume
Q	Injection quantity	$w_{1/2}$	Temporal peak width at half-height
q	Charge	ζ	Zeta potential
r_i	Radius of the ion	ZE	Zone electrophoresis
r_d	Capillary inner diameter		

Introduction

Capillary electrophoresis (CE) is one of the most powerful liquid phase separation techniques. Evolving about 30 years ago out of the traditional electrophoretic techniques, such as slab gel electrophoresis, it became a rapid alternative to high-performance liquid chromatography (HPLC) and gas chromatography (GC). The reasons for this were many and varied: high speed, high efficiency, different selectivity, and the ability to sample small volumes. There was much hype and promise and while it has not replaced HPLC and GC as was touted in the early days, it is nevertheless the method of choice in a number of key areas that are of particular relevance to forensic science that are discussed in the following article.

At its most basic level, electrophoresis is the movement of ionic species in conductive media under an applied electric field. Although much of the fundamental understanding of electrophoresis comes from around the 1900s with the pioneering work of Kohlrausch, the first demonstration of electrophoresis as a separation technique dates back to the 1930s, with the elegant moving boundary experiments of Tiselius on the separation of human serum. The separation was performed in a glass U-tube, with an internal rectangular cross-section of 3 mm × 25 mm. However, the large scale of the tube led to excessive heat production which resulted in poor resolution. To counteract this, a solid support, such as paper, starch gel, agarose, cellulose acetate, and polyacrylamide gel, was used, and of course, spawned the development of SDS-polyacrylamide gel electrophoresis (SDS-PAGE). When combined with isoelectric focusing (IEF), this created a 2D system that has been the cornerstone of proteomic studies (the separation and differential expression of proteins within a sample) for the last three decades. In the late 1970s, a different approach to overcoming the heat issue was presented in Europe by Hjerten in which narrow diameter tubes were used. Independently in North America, Jorgenson and Lukacs did the same thing, although on a much smaller scale using micron-sized fused silica capillaries developed for capillary GC, and it is this format that is implemented around the world today and is most well known for being the platform for sequencing DNA. The most recent significant advancement in the field of

electrophoresis has been its implementation in planar microchips in the early 1990s. This has taken separations that used to require hours in gels, to tens of minutes in capillaries to tens of seconds in microchips. Many of the concepts discussed here for capillaries are equally applicable to microchips (Table 1).

For more complete details of the history of electrophoresis, the reader is referred to the texts listed in the 'Further Reading'.

Fundamentals of CE

As mentioned above, the basic premise of an electrophoretic separation is that different charged species will move at a different velocity and can thus be separated. While correct on a conceptual level, the truth is that it is far more complex, as there exists a complex interplay between the analyte ions, the capillary surface, and additives placed in the electrolyte.

Electrophoretic Mobilities

The electrophoretic mobility of an ion (μ_{ep}) can be described in terms of physical parameters when the electrical force is equal to frictional force:

$$\mu_{\text{ep}} = \frac{q}{6\pi\eta r_i} \quad [1]$$

Table 1 Milestones in CE development

Year	Achievement

1992	Microchip electrophoresis, Manz

where q is the charge, η is the viscosity, and r_i is the radius of the ion. From this equation comes the notion that the speed at which an ion moves is related to its charge to size ratio ($q:r_i$). Practically, it is more useful to consider this as the charge to shape ratio, as it is the shape created by the solvated ions that really governs the frictional force and influences the mobility. It should also be obvious from this equation that the sign of the charge, that is, whether the ion is an anion or a cation, will influence the direction in which the ion moves and thus anions and cations will move in different directions. Their simultaneous separation would be nontrivial, if it were not for the very important and crucial phenomena of electroosmosis.

Electroosmosis and the Electroosmotic Flow

Electroosmosis is observed when an electric field is applied to a conductive solution in a capillary that has fixed charges on its interior wall. In a fused silica capillary, which is the most commonly used in CE, the inner surface contains ionizable silanol groups (SiOH) that have pK_a values from 4 to 6. At pH values greater than 4, silanol groups ionize giving the anionic form, silanolate (SiO⁻), and thus the surface has a negative charge. This attracts positively charged cations from the bulk solution forming a double layer with positive charge density that decreases exponentially as the distance from the wall increases. A potential difference very close to the wall will be created and this is called the zeta potential. As shown in **Figure 1**, the innermost layer close to the capillary surface is essentially static and is termed the inner Helmholtz or stern layer and the second layer is more diffuse and is termed the outer Helmholtz plane (OHP). Upon application of an electric field, cations in the second more diffuse layer migrate in the direction of the cathode; in doing so they drag associated solvent molecules along with them thus giving rise to the electroosmotic flow (EOF). The force propelling the liquid originates at the charged surface and this causes the flow to move in a 'plug'-like fashion in contrast to the parabolic profile observed when pressure is used to pump liquid (**Figure 2**). It is this difference in flow profile that is one of

Figure 1 Electric double layer in fused silica capillaries.

the main reasons for the high efficiencies that can be obtained by electrophoresis.

One of the most important implications of having EOF is that it will physically move the liquid through the capillary and the electrophoretic separation is superimposed on top of this flow. This EOF or bulk flow acts as a pumping mechanism to propel all molecules (cationic, neutral, and anionic) toward the detector with separation ultimately being determined by differences in electrophoretic migration of the individual analyte. The net apparent mobility (μ_{app}) is the vector sum of the μ_{EOF} and μ_{ep} :

$$\mu_{app} = \mu_{ep} + \mu_{EOF} \quad [2]$$

As shown in **Figure 3**, in a fused silica capillary with the EOF directed toward the cathode, cations will reach the detector fastest in the order of decreasing μ_{ep} as their μ_{ep} is in the same direction as the μ_{EOF} are acting in the same direction. Next will be neutral molecules which will migrate as a single unresolved peak with the EOF. After the EOF, the anions will emerge in the order of increasing μ_{ep} as their mobility is in the opposite direction to the EOF. It is important to note that anions with a mobility μ_{ep} greater than μ_{EOF} will never reach the detector and will migrate out through the inlet of the capillary.

The velocity of an ion (v_i) can be given by

$$v_i = \mu_{app}E = (\mu_{ep} + \mu_{eo})E \quad [3]$$

where E is the applied electric field ($V\ m^{-1}$) and is simply a function of the applied voltage (in V) and the total capillary length (L_{tot} , in m):

$$E = \frac{V}{L_{tot}} \quad [4]$$

Calculation of μ_{app} can be achieved directly from the electropherogram from

$$\mu_{app} = \frac{L_d L_t}{tV} \quad [5]$$

where L_d is the length of the capillary to the detector (in m) and t is the migration time of the analyte (in s).

Similar to the equation for the μ_{ep} , the μ_{EOF} is given by

$$\mu_{EOF} = \frac{\epsilon \zeta}{\eta} \quad [6]$$

where ϵ is dielectric constant of the medium, ζ is zeta potential, and η is solution viscosity. It follows from this equation that

Figure 2 Uniform flow profile in capillary electrophoresis.

Figure 3 Migration of solutes in capillary electrophoresis.

magnitude and direction of the EOF will be proportional to the zeta potential. The zeta potential is largely dependent on the electrostatic nature of the surface, and this is an important factor to consider when performing electrophoretic separations in microchips, which are now more commonly made in plastic via mass replication techniques. What is less obvious from eqn [4] is that it can also be affected by a number of factors such as pH, ionic strength, temperature, the electric field, and the presence of some additives. For example, with increased ionic strength there is more double-layer compression and hence a decreased zeta potential, and a reduced EOF is obtained. Using eqn [3] and using the migration time of a neutral marker, such as acetone, thiourea, and pure water, it is possible to calculate μ_{EOF} . It is then simple to calculate the value of μ_{ep} for each ion using eqn [2]. Values of electrophoretic mobility are now frequently tabulated, with the most easily accessible values obtained from the electronic database of the simulation software Peakmaster or Simul.

EOF Control

While the EOF can be beneficial for performing some separations, good control of the EOF is required to achieve the best results. The quickest and most efficient separations are usually obtained in a co-EOF mode in which the EOF is in the direction of ion mobility of interest, while the best resolution is obtained in a counter-EOF mode in which the EOF is in opposite direction to the mobility of the ions. In addition, electrophoretic separation modes such as isoelectric focusing and capillary sieving electrophoresis (CSE) often require reduction of EOF.

Controlling the magnitude of the EOF in a fused silica capillary can be achieved by simply varying the pH. At low pH, the silanol groups are protonated and there is very little EOF. At a $\text{pH} > 8$, these same groups are completely ionized giving rise to a strong EOF toward the cathode. More stable and repeatable EOF is most easily achieved through capillary wall modifications, either permanent or dynamic. Permanent wall

modification through covalent attachment is achieved through silylation followed by deactivation with a suitable functional group, polyacrylamide, polyethylene glycol, or polysaccharides, and a number of these are commercially available. An even simpler approach relies on dynamic modification of the surface by addition of an appropriate modifier to the background electrolyte (BGE). The modifier interacts with the capillary wall and in this way affects the EOF. Addition of anionic (or cationic) surfactants may increase (or decrease) the EOF. Also, neutral hydrophilic polymers that adsorb to capillary wall through hydrophobic interactions will decrease EOF by shielding surface charge and increasing viscosity. The downside of using a dynamic coating is that there is potential interaction with the analytes which may be undesirable in some instances. To overcome this, there has been considerable research over the past decade on the formation of semi-permanent capillary coatings created through the use of double-tailed surfactants or through the use of multiple layers of alternating charged polyelectrolytes. These are attractive because the capillary may need to be recoated between separations, or only once a day, and they ensure that the same exposed surface is obtained irrespective of the material allowing the same surface chemistry to be used in plastic and glass microchips and improving intercapillary and interchip repeatability.

Background Electrolytes

The composition of the electrolytes inside the capillary is typically what defines the mode of separation that occurs and the order in which peaks move past the detector. The solution chemistry requirements for the mode of separation are discussed in more detail below, but within each separation mode, variation of the composition will change the selectivity. Taking zone electrophoresis, for example, the exact composition of the electrolyte will influence the sensitivity, resolution, and separation time, as depicted in Figure 4. For example,

Figure 4 Factors affecting separation in CE.

changing the pH of the electrolyte will change the net charge of weak acids and bases which will impact upon the μ_{ep} leading to a change in resolution and separation time. pH may also change the surface charge and zeta potential of the capillary thus changing the EOF, which will also impact upon the same criteria. Changing the pH of the electrolyte will also change the ionic strength, which will impact on both μ_{ep} and EOF, thus also influencing the separation. Similarly, adding an organic solvent such as methanol will change the solvation of the ions and the viscosity of the electrolyte, which will again influence mobility and EOF.

The complexity of electrophoresis can often be daunting to the electrophoresis newcomer, but there are a number of general principles and conditions that can be used to rapidly identify the feasibility of a specific separation, which can then be further refined as necessary. Phosphate buffers at pH 2 and 7, and borate at pH 9, at a concentration of 10–50 mM are suitable electrolytes to start with as they provide a reasonable ionic strength and have excellent transmission properties for UV–vis detection. For MS detection, 1 M formic acid and acetic acid provide low pH options, while at high pH, 10–100 mM ammonium acetate/formate is the most popular option, while conductivity detection typically uses 20–50 mM HES/MES. It can also be simpler when starting to perform separations in a co-EOF manner, or in a suppressed EOF environment. Unmodified fused silica capillaries are good for cations and for anions at low pH where the EOF is suppressed. If a high pH is required

for anion separations, then reversing the EOF is easily done by incorporating a cationic surfactant (such as CTAB) into the electrolyte or by coating the capillary as discussed above. If the analytes are neutral, then a suitable additive such as SDS must be added to perform an electrokinetic chromatography (EKC) separation.

Once conditions for a basic separation have been established, there are then a myriad of electrolyte additives that can be used to enhance the separation in one way or another. This may be simply changing the type of salts used in the electrolyte (through for example, differences in ion-association interaction), changing the solvent (organic solvents and mixed solvents can provide uniquely different selectivity), and the addition of additives to alter charge or size through secondary equilibria, and various combinations of these. It is this ability to vary the position of a peak within a separation and to adjust the conditions to manipulate the system to achieve the desired outcome that is one of the reasons that electrophoresis is such a powerful separation technique. The other is the high efficiency.

Maximizing Efficiency

It is misleading to discuss theoretical plates in electrophoresis; nevertheless, it is a convenient concept to describe analyte peak shape and for comparison with other separation techniques. Efficiency is described by the number of theoretical plates (N)

Figure 5 Peak distortions due to differences in mobilities between sample and BGE.

and is related to the height equivalent to the theoretical plates (H_{th}) by

$$N = \frac{L_d}{H_{th}} \quad [7]$$

where L_d is the effective length of the capillary. The theoretical plate number can be determined directly from an electropherogram by

$$N = 5.54 \left(\frac{t}{w_{1/2}} \right)^2 = \mu_{app} \times \frac{V}{2D_m} \quad [8]$$

where t is the migration time, $w_{1/2}$ is temporal peak width at half-height, and D_m is the diffusion coefficient of the analyte.

CE has much higher efficiencies than can be achieved by HPLC, with typical plate numbers from 100 000 to 500 000 plates/m. This is primarily because CE does not have many of the sources of inefficiency that HPLC does and because of the flat plug-like profile of the EOF. Ideally in CE the zone dispersion is only due to longitudinal diffusion. In reality, inherent in all electrophoretic separations is electromigration dispersion. This arises when there is a difference in electrophoretic mobility of the analyte and the electrolyte co-ion (Figure 5). If the analyte ion has a higher μ_{ep} than that of the electrolyte co-ion, then the peak will be fronting, if μ_{ep} are equal then the peak will be symmetrical, and if the analyte has a lower μ_{ep} then the peak will be tailed. Electromigration dispersion can be decreased by matching the mobilities of the buffer constituent to the sample mobility or by maintaining a running buffer concentration approximately two orders of magnitude higher than that of the sample.

During any electrophoretic separation heat will be generated. The temperature increase depends on the power and is determined by the capillary dimensions, conductivity of the buffer, and the applied voltage. If the heat is not dissipated efficiently, temperature gradients can develop across the capillary with ions in the center of the capillary having a higher μ_{ep} than those at the capillary wall and band broadening will be

observed. This can be a significant issue when performing separations in plastic microchips that have a lower thermal conductivity than glass and cannot dissipate the heat as effectively. There are a number of methods that indicate excessive heat generation and possible temperature gradients. These phenomena may be indicated if efficiency is reduced as the voltage is increased. And, a disproportionate increase in current with voltage, Ohm's law, indicates temperature gradients. Measures to control Joule heating may include reducing the capillary inner diameter, active temperature control, or the use of low-mobility buffers which contain large, minimally charged ions, such as Tris, borate, and histidine.

One other major source of band broadening in CE is that of wall interaction. Depending on the extent of interaction, peak tailing and even total adsorption of the solute can occur. The primary causes of adsorption to the fused silica walls are electrostatic interactions between charged analytes and the charged wall, and hydrophobic interactions. Significant adsorptive effects have been observed especially for large peptides and proteins, and it is imperative to minimize these to obtain highly efficient separations. The use of zwitterionic buffer systems and pH and ionic strength extremes can be useful for overcoming these issues, but the most prominent approach is to modify the capillary wall to limit solute adsorption.

Modes of Separation in Electrophoresis

One of the highly attractive features of electrophoresis is the ability to perform a number of different types of separations through simple variation of the capillary and electrolyte chemistry. These can be classified into several separation modes, each possessing its characteristic separation mechanism. These can be implemented in both capillaries (abbreviated with a c at the front) and microchips (abbreviated with an m at the front) with the same level of ease.

Zone Electrophoresis

Zone electrophoresis (ZE) is the most widely used mode. It is fundamentally the simplest form of CE, mainly because the capillary is only filled with buffer. Separation occurs because solutes migrate in discrete zones and at different velocities and are separated solely based on differences in μ_{ep} . Both anionic and cationic solutes can be separated simultaneously by ZE due to EOF (Figure 3). However, some analytes cannot be separated by this classical version of electrophoresis because they are neutral or they may not differ significantly in electrophoretic mobility.

Electrophoretic Chromatography

To allow the separation of neutral compounds, an additive is added to the electrolyte which forms a dispersed phase moving at a different velocity with which the analytes interact. In order to achieve separation, either the analytes or this secondary phase should be charged. One of the main attractions of EKS is the simplicity with which the system can be varied. The nature of the additive governs the type of interaction while the concentration controls the capacity, thereby providing considerable scope for optimization. This has several advantages over chromatography, notably that neutral species migrate between the EOF and the additive and thus there is no infinite migration time, and that the entire contents of the capillary can be removed after each separation rather than waiting for the last peak to emerge from the column as is required for HPLC. While initially developed to allow neutral analytes to be separated by electrophoresis, it can also be used to improve the resolution of charged analytes.

Micellar electrokinetic chromatography (MEKC) was first used to demonstrate the separation of neutral compounds by CE where the secondary phase is a micelle dispersed in the BGE. A potential problem with the use of ionic surfactants, especially at high concentrations, is the increase in current. Even with narrow bore capillaries (25–50 μm) the use of extremely high electric fields is often avoided and efficient capillary thermostating is necessary. In microemulsion electrokinetic chromatography (MEEKC), a microemulsion droplet is employed as the dispersed phase. Microemulsion droplets, either oil-in-water or water-in-oil, are thermodynamically stable transparent nanodroplets stabilized by surfactants and co-surfactants. The microemulsion droplets are more flexible and can swell better than micelles, providing a wider separation window and a higher resolution. However, preparation of the microemulsion can be complicated and time consuming and not all microemulsions have suitable stability.

Chiral electrokinetic chromatography allows the separation of enantiomers by using a chiral selector as an additive. Charged and neutral cyclodextrins, macrocyclic antibiotics, crown ethers, chiral metal complexes, and chiral surfactants have all been used to form dynamic diastereomeric complexes that can be separated. This is a particularly powerful application of CE as the type and concentration of chiral selector can be easily changed in order to optimize the separation of a specific enantiomeric pair at much lower cost than can be achieved by HPLC and GC. The ability to separate enantiomers is of particular importance in some forensic applications

where one enantiomer is legally allowed while the other is not. Examples include the isomers of 3-methoxy-*N*-methylmorphinan, propoxyphene, norpseudoephedrine, and cocaine, as well as compounds in which there is a more significant physicoactive response from one isomer over the other, for example, with amphetamines. These types of applications (and others) are discussed in more detail elsewhere in the Encyclopedia.

Sieving Electrophoresis

Sieving electrophoresis (SE) involves the addition of a sieving medium to the background electrolyte. The separation is based on differences in size and shape of the charged analytes and is particularly useful for the separation of large biological molecules such as proteins and DNA. Most commonly used today are solutions of water soluble polymers (such as linear polyacrylamide and LPA) that form an entangled network through which the analytes migrate. These have a low viscosity and can be replaced between each separation thus providing improved repeatability and performance. They also overcame many of the issues with capillary gel electrophoresis in which the capillary is filled with a cross-linked gel (such as an acrylamide gel). CSE was the basis of a generation of DNA sequencing instrumentation and can be performed on commercial instrumentation featuring 96 individual capillaries for high-throughput sequencing and is most commonly used within the forensic community for DNA profiling based on the CSE separation of PCR amplified STRs.

Electrochromatography

Electrochromatography (EC), as the name implies, is a combination of CE and HPLC in which there is a heterogeneous phase inside the capillary. This can be achieved through a capillary, filled, packed, or coated with a stationary phase, and the migration is determined by a combination of electrophoretic migration and chromatographic retention. There are many practical difficulties in performing CEC, but it is attractive when using MS detection as many EKC methods are not compatible with this method of detection.

Isoelectric Focusing

Isoelectric focusing (IEF) is an electrophoretic technique for the separation of amphoteric analytes according to their isoelectric point (pI) by the application of an electric field along a pH gradient formed in a capillary. In contrast to most modes of electrophoresis, the whole capillary is filled with a mixture of sample and ampholyte mixture and each analyte is focused at its pI. It is a high-resolution technique and can be used to separate proteins that differ by 0.005 pI units and less. The protein zones remain narrow because a protein which enters a zone of different pH will become charged and migrate back.

Isotachopheresis

Isotachopheresis (ITP) involves the injection of the sample between a leading electrolyte and terminating electrolyte. When the voltage is applied, the analytes that have a μ_{ep}

bracketed by the leader and terminator form zones in order of decreasing mobility with the length of the zone proportional to the concentration of that analyte. ITP is particularly powerful for trace analysis as low abundant components have their concentration adjusted up to the steady-state ITP plateau concentration defined by the composition of the leading electrolyte.

Instrumentation and Sample Handling

All the above modes of electrophoresis can be performed in essentially the same instrumentation in capillaries and microchips, but there are some differences in hardware between the two platforms. A schematic for CE is shown in Figure 6. The closed circuit is composed of a high-voltage power supply (5–30 kV), two electrodes, two buffer reservoirs, and the separation capillary (typically 25–75 μm i.d.). Sample is introduced into the capillary from one end by pressure, vacuum or by voltage. A detector is used to monitor the separated analytes through a window made on the capillary wall.

The capillary column is a key element of the CE separation. Fused silica is by far the most frequently used material, although columns made of Teflon and other plastic materials can also be used. The wide spread use of fused silica is due to its intrinsic properties, which include good optical transparency making absorbance detection easily feasible over a wide range of UV and visible wavelengths. Fused silica is also easy to manufacture into capillaries with diameters of a few micrometers.

Sample can be introduced into the capillary in two common ways in CE. In hydrodynamic injection, a pressure difference between the inlet and outlet is applied to move the sample into the capillary. The injection volume (v_{inj}) can be calculated by the following equation:

$$v_{\text{inj}} = \frac{\Delta p \pi r_d^4 t_{\text{inj}}}{8 \eta L_{\text{tot}}} \quad [9]$$

where Δp is the pressure difference, r_d is the capillary inner diameter, t_{inj} is the injection time, and η is the viscosity of the buffer. With hydrodynamic injection, the quantity of the sample loaded is nearly independent of the sample matrix.

In electrokinetic injection, a voltage is applied across the capillary and solutes enter the capillary due to μ_{ep} and μ_{EOF} . The injection quantity (Q) of a component can be given by

$$Q = \frac{(\mu_{\text{ep}} + \mu_{\text{eo}}) \pi r_d^2 V t_{\text{inj}} c}{L_{\text{tot}}} \quad [10]$$

where c is the concentration of the component in the sample solution. Variations in conductivity, which can be due to matrix effects such as a large quantity of an undetected ion such as sodium or chloride, result in differences in voltage drop across the sample and hence the quantity loaded. Owing to these phenomena, electrokinetic injection is generally not as reproducible as its hydrodynamic counterpart, but this can be easily corrected for with the use of an internal standard.

Instrumentation for ME is slightly different (Figure 7). The power supply is typically smaller, from 3 to 10 kV; there are four reservoirs on the microchip, 3 of which house buffer with sample in the other. Injection is performed at the intersection of two microchannels interconnected in a 'cross' and so far, fluorescence detection is the most common form of detection. The chip material has significant implications on the separation, and can be either glass or plastic, with the latter preferred due to the ability to produce them quickly and cheaply in commercially viable quantities.

Sample Concentration

One of the major limitations of electrophoresis is its high limits of detection. This arises from the small dimensions of

Figure 6 Basic capillary electrophoresis instrumentation.

Figure 7 Schematic diagram of CE microchip and sample injection; buffer inlet (B), buffer waste (BW), sample inlet (S), and sample waste (SW).

the capillary and microchip, which limit both the volume of the sample that can be injected and the optical pathlength when spectrophotometric detection is used. In general, the injected sample plug is usually 1% of the total separation length to maintain high efficiency. This translates to injection volumes of approximately 0.5–50 nL. It is possible to inject more than this, but the analytes must be concentrated or stacked to preserve separation efficiency and avoid overloading. A number of online approaches have been developed to address this issue and are based on either chromatography through integration with solid-phase and liquid-phase extraction or electrophoresis through changes in analyte velocity. Electrophoretic methods are far simpler to implement than those based on chromatography and a number of powerful methods have been developed, which are collectively known as stacking. Field-amplified sample stacking (FASS) is the simplest method for online preconcentration as it is induced by injecting the sample dissolved in sample that has conductivity at least ten times lower than that of the BGE. This causes a higher electric field strength to fall over the sample and the ions migrating through a low conductivity solution into a high-conductivity BGE slow down at the boundary of the two solutions and 'stack' into a narrow zone. There are a large number of variants based on large volumes and exploitation of ITP and IEF phenomena. These approaches can all improve detection limits by 100–1000. An alternative approach developed for EKC, called sweeping, relies on the accumulation of the analytes by the additive as it moves through the sample. This has been shown to be suitable for both charged and neutral solutes and can improve detection limits by 100–1000. When these strategies are employed with electrokinetic injection, then it is possible to improve detection limits by 1 000 000-fold.

Detection Methods

There are several detection methods available with the most common compared in Table 2. These can be either performed on-capillary or end-capillary. On-capillary (and on-chip)

detection involves detection of the analytes as they migrate through the capillary/microchannel, and is typically performed with either spectrophotometry or contactless conductivity detection. End-capillary detection is performed on the effluent of the capillary, which is focused or collected into the detector and is required for some forms of detection, such as mass spectrometry. On-capillary detection such as this reduces peak distortion and loss of resolution that can be observed in end-capillary methods.

Spectrophotometric methods

Spectrophotometric detection is achieved by monitoring the change in light induced by the target analytes as they migrate through a detector. When performed on-capillary, however, sensitivity is limited by the small capillary internal diameter, which defines the path length. UV–vis absorption is the most widely used detection method in capillaries as it is cheap and has wide applicability and most commercial instruments now come equipped with diode array detectors allowing monitoring at multiple wavelengths and the collection of full spectra. It is not widespread in microchips primarily due to the significant UV absorbance of many microchip materials and the difficulty in obtaining long pathlengths.

The problem of low sensitivity can be partially solved through the use of laser-induced fluorescence (LIF). Detection limits as low as 10^{-14} to 10^{-18} mol have been reported; however, the major drawback is that most analytes do not fluoresce well and must be derivatized with fluorescent reagents first to improve sensitivity. This has been most widely implemented in microchips.

Mass spectrophotometric detection

Mass spectrometric (MS) detection is the most powerful detection technique and is becoming increasingly important in forensics for the absolute identification of components and its ability to differentiate overlapping peaks with distinct mass-to-charge ratio (m/z). It can be interfaced off-line with matrix-assisted laser desorption/ionization (MALDI); however, it is far more common to interface online with electrospray

Table 2 Common detection methods for capillary and microchip electrophoresis

Method	Mass detection limit (mol)	Concentration detection limit (M) ^a	Advantages/disadvantages
UV–vis absorption	10 ^{−13} to 10 ^{−15}	10 ^{−5} to 10 ^{−8}	● Universal ● Diode array offers spectral information ● Not common in microchips
Laser-induced fluorescence	10 ^{−18} to 10 ^{−20}	10 ^{−14} to 10 ^{−16}	● Extremely sensitive ● Usually requires sample derivatization ● Expensive
Amperometry	10 ^{−18} to 10 ^{−19}	10 ^{−10} to 10 ^{−11}	● Sensitive ● Selective but useful only for electroactive analyses ● Requires special electronics and integrated detection electrodes
Conductivity	10 ^{−15} to 10 ^{−16}	10 ^{−7} to 10 ^{−8}	● Universal ● Simple when implemented in contactless mode
Mass spectrometry	10 ^{−16} to 10 ^{−17}	10 ^{−8} –10 ^{−9}	● Sensitive and offers structural information ● Interface to MS nontrivial
Indirect UV, fluorescence, amperometry	10–100 times less than direct method	–	● Universal ● Lower sensitivity than direct methods

ionization (ESI). Interfacing CE to MS is much more difficult than LC due to the smaller volume of effluent and also the need to maintain a stable electric circuit for electrophoresis, and highly sensitive and robust interfaces are required before this detection technique will become widespread. Microchips can be interfaced directly to the MS, but there are even more significant issues than with capillaries.

Electrochemical detection

Electrochemical detection (ECD) can be carried out in either on-capillary or end-capillary. It can be classified into amperometry, conductimetry, and potentiometry according to operation principles. Amperometry is the most sensitive, but it is only responsive to electroactive analytes. For conductivity detection, a major consideration is selection of the appropriate BGE to maintain conductivity differences between the BGE and the analytes. At the same time, mobility differences between the analyte ions and co-ions in the BGE should be minimal to obtain symmetric peaks. The development of noncontact contactless conductivity detection has seen recent growth in this form of detection. It is interesting to note that due to the ability to easily integrate electrodes in microchips, ECD is actually easier to implement in microchips than in capillaries.

Future Directions

Electrophoresis in the capillary format is nearly 30 years old, whereas in microchips it is nearly 20 years old. Yet there are still a number of issues that have yet to be resolved. There is no doubt that there will be a continued drive toward the microchip platform, particularly through the integration of sampling handling to make a so-called ‘micro-Total Analysis System’ (μTAS). Many of these have already begun to appear with the biggest market being that in the field of DNA analysis, and there are already numerous microchip systems describing the integration of extraction, amplification, and separation in a

single microchip. But these devices are highly complex and far from routine use and considerable development needs to occur before these will become widespread. It is also necessary to note that many of the issues that have limited the applicability of CE, such as sensitivity and repeatability, are even more problematic in microchips, and these have yet to be resolved. Finally, interfacing both capillaries and microchips with MS does need to have a robust, sensitive, and reliable solution, and while there has been significant development in this area, there is still as yet no commercially reliable interface that can match the sensitivity and performance achieved with LC-MS.

Glossary

Allele Any of the forms of the same gene that occur at the same locus on a homologous chromosome but differ in base sequence.

Amplicon A small sequence of DNA that has been amplified by PCR.

Autosomal STR Any STR located on the autosomal chromosomes (i.e., nonsex chromosomes).

Deoxynucleotide triphosphate (dNTP) A monomer, or single unit of DNA or deoxyribonucleic acid.

Loci (singular locus) The specific position, in all homologous chromosomes, of a particular gene or one of its alleles.

Multiplexes The simultaneous amplification of two or more DNA targets in a single PCR reaction.

Polymerase chain reaction (PCR) A method whereby a specific sequence of nucleotides within a double-stranded DNA is amplified.

Polymorphism The regular and simultaneous existence in the same population of two or more alleles, at a frequency existing in more than 1% of the population, that cannot be due to recurrent mutations.

Primer Short, synthetic fragments of single-stranded DNA that are complementary to DNA sequences that flank the target region to be amplified by PCR.

Short tandem repeat or microsatellite (STR) A DNA sequence from 2 to 6 nucleotides which are tandemly repeated from 5 to 5000 times.

Single-nucleotide polymorphism (SNP) A single nucleotide position in a genome sequence at which alternative alleles are present at an appreciable frequency within a population.

Introduction

This article aims to highlight the changes in the methodology and use of capillary electrophoresis (CE) by forensic biologists since the publication on the same subject by McCord and Buel in the first edition of the Encyclopedia of Forensic Sciences over 10 years ago. The main focus will be on the current status of CE applications by forensic biologists, summarizing the main processes and factors involved in performing CE for a range of marker systems. This article will conclude with a brief consideration of what the near future may hold for CE in forensic biology.

CE Methodology

Since its development in the 1980s, CE has become widely used throughout molecular biology to separate and detect ionic molecules based on their size and charge. Compared to other methods of detecting genetic variability (such as mass spectrometry (MS), high-performance liquid chromatography (HPLC), and probe-based hybridization), CE offers reproducible results with high sensitivity, resolution, and precision, with the additional advantage of being fully automatable for high-throughput sample analysis, and being relatively low cost. Although forensic laboratories had previously used autoradiography, slab-gel electrophoresis (such as the Hitachi FMBIO Scanners or ABI 377), or UV-based CE (with the Beckman P/ACE instruments), the vast majority have now moved to multicolor laser-based detection with the Applied Biosystems ABI Prism 310, 3100/3130xL, or

the newer 3500xL Genetic Analyzers. The increased flexibility and throughput has enabled laboratories worldwide to accommodate the ever-increasing numbers of samples submitted for forensic profiling, as well as expand the numbers and types of markers analyzed.

The basic components of a CE system are similar regardless of the type or model employed. These include a variable high voltage power supply (0–30 kV), a fused silica (SiO₂) capillary, with a 330-μm external diameter and an internal diameter of 25–75 μm, two buffer reservoirs, two electrodes, and an on-capillary detector (Figure 1). Although there are multiple techniques and chemistries for each stage of the CE process, only those most commonly employed in forensic laboratories will be described in detail below. These can be separated into three broad stages – injection, separation, and detection.

Injection

One of the main advantages of CE is its ability to inject extremely small volumes of sample. All CE systems currently in use employ an electrokinetic injection system to introduce the molecules to the capillary for separation. An electric voltage is applied to the end of the capillary while it is immersed in the deoxyribonucleic acid (DNA) sample. The negative charge of the DNA, combined with the flow of current from the applied voltage, draws the DNA into the capillary. The amount introduced is dependent on the mobility and concentration of the DNA, the injection time, the voltage applied, and the ionic strength of the sample in comparison to the buffer used for electrophoresis. Altering any of these factors will result in an

Figure 1 Schematic illustration of capillary electrophoresis systems used for DNA analysis.

alteration in the amount of DNA introduced to the capillary. It should be noted that the presence of competing negatively charged ions, such as chloride ions from the polymerase chain reaction (PCR), will alter the sample conductivity, and thus the injection properties. As these ions are smaller than the DNA molecules to be analyzed, they will be introduced preferentially. Purifying the PCR product with silica spin columns or dialysis effectively reduces the concentrations of competing ions, unincorporated primers, and deoxynucleotide triphosphates (dNTPs), ensuring maximal injection of the target DNA. The dilution of the PCR reaction in high-quality formamide can aid in reducing the concentration of competing ions, and also denatures the DNA to ensure reproducible migration times. Purification and the use of formamide also increase the amount of sample injected by facilitating the stacking of the molecules, resulting in a sharper injection zone (Figure 2). When the ionic strength of the sample is lower than that of the buffer within the capillary, the strength of the electric field created by applied voltage is maximized at the interface of the sample and buffer. This field effectively mobilizes the DNA, forcing them to move rapidly toward the capillary and form a narrow 'stack' at the interface. Stacking results in rapid, efficient separation, and minimizes the diffusion of the migrating sample producing a sharper band. However, the differing mobility of each type of molecule during electrokinetic injections and stacking means that the process is qualitative only – the concentrations of molecules injected can differ greatly from those in the original sample.

Although not employed on CE instruments currently in use in forensics, hydrodynamic injection is another method available. The application of a pressure difference between the two ends of the capillary results in DNA being introduced in amounts relative to the injection time, the pressure difference, the sample viscosity, and the inner diameter of the capillary. As this method does not rely on sample conductivity, ions present in the sample do not affect the injection process, resulting in a more reproducible, and thus quantitative, method. However, the wider injection bands given with hydrodynamic injections give poor resolution, preventing accurate sizing of products.

Separation

The efficient separation of analytes is not only controlled by the matrix in which separation is achieved, but also the type of capillary employed, the electrophoresis buffer, and the strength of electric field applied during the process.

Modern CE instruments utilize entangled polymers to ensure maximal separation, giving superior results to the previously used cross-linked polyacrylamide and agarose gels. Entangled polymers, such as the polydimethylacrylamide POP-4, -6, and -7 from Applied Biosystems, act as molecular sieves that retard large molecules as they pass through the pores formed by the polymer. DNA molecules smaller than the pores can migrate rapidly by Ogston sieving, with the rate of movement proportional to their ability to find and pass through pores. Molecules larger than the pore size move through the polymer by reptation – elongated DNA molecules 'snake' through the pores, in a considerably slower process. While POP-4 is suitable for short tandem repeat (STR) and single-nucleotide polymorphism (SNP) typing, the higher polymer concentrations in POP-6 and POP-7 provide greater resolution for DNA sequencing.

Capillaries used in Applied Biosystems' CE instruments are composed of uncoated silica, with a length of 36 cm most commonly used for STR and SNP analysis. While the lack of coating aids in detection, it can result in electro-osmotic flow (EOF) during electrophoresis. Charged silanol groups on the interior of the capillary can force the solution to flow toward the negative electrode, impeding the separation of DNA. The induction of EOF is suppressed when using POP polymers, as they mask the charged sites on the capillary walls and provide a viscous layer to resist the flow. Over time however, contaminants can build up on capillary walls, creating a double charge layer and inducing EOF. For this reason, uncoated capillary arrays are useable for limited numbers of injections before reproducibility in migration times declines.

Detection

Fluorescence-based detection is now the most commonly used method within forensic laboratories. As multicolor detection

Figure 2 Schematic illustration of the CE process. Electrokinetic injection introduces the DNA to the capillary via sample stacking. During migration through the capillary, separation is achieved via Ogston sieving for small molecules, and reptation for the large molecules. Detection of the fluorescent dyes is performed by an argon/diode laser, with the raw signal deconvoluted relative to prior spectral calibrations to produce the separated fluorescent signals for each dye.

has developed (from 4 to 5 with the ABI 310 and 3100 series, to 6 with the ABI 3500 series), highly multiplexed assays have become possible. By attaching a fluorescent dye label to the 5' end of one in the PCR primer pair for each locus, laser detection can be utilized, and with multiple dyes, loci with overlapping allele size ranges can be analyzed simultaneously. Combinations of rhodamine and fluorescein dyes, designed to absorb light at a single wavelength but emit at different wavelengths, are typically used. Newer fluorescent dyes (such as 6-FAM and VIC) have increased levels of fluorescence compared to the older 5-FAM and JOE, and as such have aided in increasing the sensitivity of current STR amplification kits.

Older CE machines (ABI 310 and 3100 series) use an argon ion laser to excite the fluorophore at 488 and 514 nm, while the newer 3500 series of CE instruments utilize a solid state diode laser exciting at 505 nm. The diodes are considerably more efficient than the older argon lasers, with a smaller size and power consumption, and greatly increased longevity. Following excitation, the emission spectra of each dye is detected with a charge coupled detector (CCD) camera as it migrates past the capillary detection window. The signal must then be deconvoluted by comparison to a reference spectral matrix to separate the individual spectra of each dye (due to overlapping excitation/emission spectra between the fluorophores), to place the signal into the appropriate color. The level of fluorescence detected is proportional to the number of dye molecules present, and thus the relative concentrations of each product can be determined. To size the molecules, an internal standard of known size fragments, labeled with a dye different from those of the unknown fragments, that span the anticipated

size range of the unknown fragments must be included and run simultaneously with the sample. Allelic ladders, composed of multiple fluorescently labeled PCR products of known alleles for each locus within the multiplex can aid in accurate allele designation, although they are not strictly necessary due to the reproducible migration of DNA fragments within modern CE systems.

Interpretation of Electropherograms

With any fluorescence-based measurement, there is a certain level of background noise present which must be accounted for when interpreting the signal. The level may differ between instruments, due to slight differences in CCD cameras and laser effectiveness and alignment. It may also change within the same instrument over time, due to the build up of contaminants within the capillaries, pump, and capillary detection window. In addition to changing the level of the baseline, these factors may also interfere with the detection of the fluorescent signal, reducing the efficiency of detecting the target. Due to these variations, it is customary to impose two thresholds on the interpretation of signals – an analytical and a stochastic threshold. The analytical threshold is the average fluorescent signal (converted to peak height) from nonallelic peaks, plus 3 (or more conservatively 10) standard deviations. This ensures that minor noise peaks are not called as genuine signals during genotyping. The stochastic threshold represents the level below which signals cannot be used to determine the true genotype present – for example, designating a locus as homozygous or heterozygous. Although the peak heights are a

reflection of the amount of DNA template added to the PCR, at lower levels of template the amount of product may be insufficient to create equal amplification between and within loci. Thus, the stochastic threshold is used to ensure these biases do not result in incorrect genotyping in the presence of allele drop-out or over-amplification. Dilution series of representative samples may be used to set the stochastic threshold, with the limit being set at the peak height at which a heterozygote can be reliably detected without one of the alleles falling below the analytical threshold. In addition, sizing precision cutoffs may be required to monitor differences in migration times between runs and instruments. Although identical alleles will generally have sizes within 0.15 bp of each other, variations in temperature, formamide, or instrument cleanliness can cause increased variation in migration times. Imposing a sizing precision cutoff around allelic genotyping size ranges can aid in detecting samples which have been affected by these factors during electrophoresis.

Recent Developments in CE

In addition to the development of improved polymers for separation, the increased dye fluorescence and the inclusion of diode lasers mentioned above, there have been other key improvements in CE in recent years. High-throughput instruments are now available, with 4–96 capillary formats. This represents a significant increase from the original single capillary ABI 310, enabling forensic laboratories to process samples substantially faster. The time required for fragment analysis has also decreased, from 45 min per injection with the 3100 to 35 min on the 3500. All these advances have enabled the total analysis time to decrease from 48 h for 96 samples with the ABI 310 to 2.5 h for 96 samples on a 24-capillary 3500xL, to only 35 min with a 96-capillary 3730xL.

The 3500 series has also introduced a new feature to CE, providing the ability to normalize fluorescent signals between samples, injections or even instruments. This allows the elimination of natural variations that occur between runs in injection or detection efficiency, or to minimize variations in peak heights caused by pipetting errors within individual samples. However, as normalization alters peak heights by up to threefold, low-level mixtures may artificially appear to be single source, or artifact peaks may appear above the analytical threshold defined during validation studies. As such, there are some concerns about the appropriateness of normalization (as it is currently done) for casework samples, and the impact this may have on interpretation.

CE Typing Methodologies Used by Forensic Biologists

STR Typing

The primary use of CE by a forensic biologist is for the typing of STRs from biological samples to generate a profile from highly polymorphic genetic markers which differ between individuals. Such profiles can be generated from almost any biological fluid or tissue. In the main, they are generated from: crime scene samples such as dried stains of blood, semen, or saliva, skin deposits (touched objects), and hair roots collected from a wide array of exhibit types; known person and convicted

offender samples such as mouth swabs; or disaster victim and missing person identification related samples that could include any of the above as well as tissue or bone samples. The ability to individualize samples is determined by the level of polymorphism of individual STR loci and the number that are used to generate a profile. The forensic community has judiciously selected a small set of STRs that are to be used to create profiles. This allows comparison of generated profiles among samples from the same case, different cases, laboratories, jurisdictions, countries, and over time. Twelve years ago, forensic biologists were just starting to implement methodologies whereby multiple loci could be amplified and typed simultaneously saving precious sample and providing labor efficiency gains. The early multiplexes amplified three or four loci that had an average combined match probability in the realm of ~ 1 in 1000 to ~ 1 in 10 000. However, multiplexes have now been expanded to contain 9–21 STRs, greatly increasing the discrimination power (with combined match probabilities in the realm of 1×10^{-11} to 1×10^{-27}). Most of the individualization kits in current use also include a sex marker, Amelogenin, located on the X- and Y-chromosomes (different lengths on each) to assist in determining if the sample originates from a male or a female.

The use of PCR to amplify STRs has significantly improved the ability to generate profiles from smaller quantities and poorer quality DNA compared to previous methodologies. While this methodology also has its limits, these too are being extended. The ability to generate profiles from trace samples has improved through the optimization of kit buffers, improved primer design and the use of increased number of amplification cycles. To increase profiling success rates from highly degraded samples (these may be encountered when dealing with very old samples, and samples exposed to extreme conditions such as fire, water, or burial) kits have been designed to incorporate re-engineered primers that bind closer to the relevant core repeat unit sequences thus generating a shorter amplicon. These shorter amplicons still include all the repeat units allowing the allele to be identified (i.e., concordance with typings for the same loci using different primers).

To enable the incorporation of so many loci, often with similar sizes, within a single assay has required considerable research and development into multiplex design and optimization. Combining up to 34 primers within a single reaction requires extremely precise design to avoid spurious interactions occurring between pairs of primers, or between primers and nontarget sections of the genome. The use of smaller amplicons also complicates design, as there is less choice for primer sequences. This inevitably leads to some compromise in the placement of primers, with some primers displaying lower amplification efficiencies than others. This can be rectified by careful selection of fluorescent dyes for each primer pair, in addition to altering relative primer concentrations. As the common dyes differ considerably in fluorescence intensity, STRs which amplify poorly can still be reliably detected by using the most sensitive dye, while those STRs that display increased amplification relative to the others can be balanced by using a dye with lower fluorescence. In this way, the signal received during CE is approximately equal between all loci and dyes.

While highly discriminating, there are specific situations where the use of autosomal STRs are not effective in

individualizing the person of interest. This includes situations where the target DNA is a very minor component within a mixture of multiple DNA sources which cannot, or has not, been differentially extracted. This type of situation occurs frequently when dealing with sexual offense related samples. In such circumstances the use of Y-chromosome STRs can be of assistance in identifying males. Commercial Y-STR multiplexes with 9–23 Y-STRs are available, but as the majority of the Y-chromosome is inherited as a block through the male lineage only the frequency of the genetic profile in the population can be used as a statistic, and is thus not as powerful as the autosomal derived STR profiles. As individual Y-STRs are (usually) homozygous, their analysis is simplified compared to autosomal STRs, without the possibility of false homozygous genotypes being reported.

For kinship analysis, X-chromosome STRs can be used to examine relationships, particularly in deficiency cases. For example, in a father/daughter paternity case without any maternal relations available, X-STR analysis can be considerably more instructive than autosomal STRs. To date, 53 X-STRs spread across the chromosome in four linkage groups have been described for forensic use.

All of the different STR systems are commonly analyzed with similar CE methods, with a 36 cm capillary and POP-4 polymer to provide single-base resolution between alleles. Commercial STR multiplex kits generally produce extremely reproducible results, with migration times (and therefore derived sizes) similar between samples, injections, and instruments. However, instrument artifacts may interfere with genotyping STR alleles if run conditions are nonoptimal. Transitory increases in voltage during the electrophoresis stage, bubbles in the capillary, or crystallized polymer can result in spikes appearing in the electropherogram. These are non-reproducible between runs, and generally can be recognized by the sharp narrow peak morphology. Dye blobs, created from unbound fluorescent dye molecules, may be present in all samples amplified with the same primer stock if primer purification during synthesis was incomplete. Each dye has a reproducible migration, and can thus be identified by its presence in all amplified samples, including negative controls.

Mitochondria Typing for Individualization

In extremely degraded samples, where the nuclear DNA is unable to provide a profile, mitochondrial DNA (mtDNA) profiles can be generated as an alternative. The mtDNA has a structure that is more robust than nuclear DNA and as it has tens or hundreds of copies per cell, the target sequence is present in far higher quantities than nuclear DNA. To obtain a mtDNA profile, forensic biologists sequence the 342 bp Hypervariable I and/or 268 bp Hypervariable II regions or alternatively just type for SNPs at specific sites within these regions. The generated profiles, however, have very poor discrimination potential relative to what STRs can provide. As they are inherited via maternal lineages these profiles have limitations in that they are unable to distinguish among maternal relatives. mtDNA profiling is more widely used in paternity testing, disaster victim identification or historical reconstructions. For sequencing, the use of POP-6 or POP-7 polymers for CE is recommended, as this will provide considerably enhanced

base resolution. Depending on the size of the amplicons, the capillary used may also need to be lengthened, to 50 or 80 cm, to ensure the complete sequence is obtained. Purification of the sequencing product prior to CE analysis is critical for successful analysis, as unincorporated fluorescent dideoxy nucleotides will severely impact on the quality of the sequencing trace.

SNP Typing for Individualization

SNPs have been identified and advocated as a replacement for STRs for individualization purposes, partly because they should allow useful profiles to be obtained from highly degraded samples. However, for various reasons these are not in regular use by forensic biologists. These include: the need to multiplex many more loci to gain the same discrimination potential as STRs which is methodologically challenging; the need for consistency in profiling systems, as moving to a new profiling system would require retesting all existing samples with the new system (which in many instances would not be possible due to the unavailability of the sample), or testing all new samples with both systems at great expense; and finally, the improvements in the engineering of the core STR systems and typing methodologies have increased the ability to generate STR profiles from highly degraded and trace samples, so the gains made by moving to SNPs would be minimal. The currently used STR systems serve the forensic biologists well.

SNPs do however provide a useful tool to forensic biologist for other purposes. STRs do not provide any phenotypic information about the individual that may be of assistance to criminal investigations. Specific SNPs can be typed that help identify features of an individual which could be highly useful to investigating officers for identifying potential suspects, or reducing the number of individuals within a suspect pool. These include SNPs that can help determine biogeographical ancestry and those that can help reveal externally visible traits.

SNP Typing for Biological Ancestry and Physical Identification Typing

Unlike SNPs used for individualization, which vary randomly between individuals, ancestry-informative SNPs have clearly defined distributions across human populations. Due to their evolutionary history and mode of inheritance particular Y-chromosome and mtDNA SNPs can clearly reveal the continental and population origins of an individual. These markers have been extensively utilized to aid our understanding of human migration and evolution. While highly informative, reliance on just Y-chromosome and mtDNA SNPs can be limiting depending on the sex of the individual, or if the individual has an admixed biological ancestry. Whole genome SNP analysis, covering hundreds of thousands of SNPs, is revealing many population specific autosomal SNPs which could be used to create panels to identify the biological ancestry of the sample donor. The use of these types of markers to assist investigators has been demonstrated to be useful but has not yet been adopted as a routinely used tool by the wider community of forensic practitioners. Further investigations of relevant markers for relevant populations, development and validation of optimized kits, and demonstrated successes of their

utilization, should see these types of markers/kits being employed more in the future.

While still in its infancy, SNPs strongly associated with genetically controlled physical features of relevance to forensic investigators are beginning to be discovered. This is being greatly assisted by the increased knowledge of the genetics underpinning particular traits and the availability of whole genome SNP data of individuals with different physical traits. SNPs associated with particular hair colors have been available for some time and have been utilized in forensic case work. SNPs strongly associated with specific iris colors have also been identified and are starting to become available for forensic investigation applications. Markers for other physical features are being sought but extensive further investigations are required before suitable markers are found, accurate and robust typing systems developed, and these then routinely utilized by forensic practitioners.

Genotyping SNPs with CE, although similar to STR genotyping, has its own specific methodological challenges which must be considered. The single base extension method of SNP genotyping has the distinct advantage that amplicons can be extremely small. However, it is inadvisable to reduce the extension primer below around 20 bases in size, as migration times and sizing can be inexact at this low size. In addition, incomplete purification can leave large dye blobs which can obscure allelic peaks at these low sizes. Although many laboratories use POP-4 successfully for SNP genotyping, POP-6 or POP-7 can provide sharper resolution, allowing for smaller size differences between loci during the multiplex design.

Other Uses

Other uses for CE are emerging including the detection of specific mRNA fragments to help identify the biological fluid or tissue origin of a forensic sample. While not yet in common use, this has the potential to replace a variety of existing chemical and immunological tests with a single efficient, highly specific, and highly sensitive methodology. This methodology also has the capacity to expand the types of biological fluids and tissues that could be readily identified, thus enhancing the forensic biologist's tool kit to assist criminal investigations. For forensic usage, many assays have been developed to use CE analysis, rather than the more common quantitative real-time PCR (qPCR) methods. Although this reduces the ability to accurately quantitate the amount of the specific mRNA transcript present, there are benefits to CE processing. As the number of dyes available, and simultaneous detection of these, is greater in CE, large multiplexes with many mRNA targets can be created and analyzed in a single assay, whereas qPCR is limited to 2–3 transcripts per assay. This not only limits sample consumption, but also allows greater throughput. The analysis of mRNA with CE utilizes the same fragment analysis protocols as STR typing, allowing the use of common electrophoresis and genotyping methods.

The Future of CE in Forensic Biology

As the number and types of markers analyzed grows within forensic biology, so too will the need for sensitive, reliable, and

rapid detection techniques. Although CE is firmly entrenched as the method of choice for all current analyses, there are many new possibilities on the horizon. Microchip CE is certainly a leading possibility to allow rapid genotyping at crime scenes in the future. In current models of these devices, 7–16 cm channels are etched in glass wafers, allowing PCR products to be separated within a linear polyacrylamide matrix. Separation can be completed in only 30 min, with single-base resolution achievable from the commercial STR kits. The addition of biotin labels to PCR primers additionally allows on-chip PCR product purification, saving time and preventing ionic interference. The recent development of microfabricated devices for DNA purification, PCR amplification, and CE has enabled the production of portable microchip analysers capable of real-time DNA analysis for use at crime scenes. However, these tools have not yet been adopted by the community, possibly due to decreased sensitivity and reliability compared to conventional analyses.

MS offers an alternative to CE, separating amplicons in only seconds, with extremely reproducible sizing of STR alleles. In addition, time-of-flight MS can provide information on internal sequence variations, increasing discrimination power by 20–30%. Although undoubtedly useful, the dominance of CE within forensic biology and the high cost of MS instruments has limited the adoption of MS for genotyping purposes. However, as the use of SNPs increases in forensic biology, it is possible that high-throughput, MS-based SNP genotyping methods such as Sequenom MASSArray will become more widely used. Unlike the current SNaPshot methods where a maximum of 20–25 SNPs can be multiplexed, Sequenom can readily cater for 40–50 SNPs per assay. At present, a minimum of 5 ng of DNA is required per assay when typing for SNPs using MS-base SNP genotyping methods, which diminishes its use for many forensic type samples, although the sensitivity may increase as the technology develops. Although an extremely useful tool for efficient SNP genotyping, it cannot be used for STR genotyping, and as such is not likely to be exclusively used as CE has been.

Similarly, next generation sequencing techniques have the potential to provide sequence variant information and increased accuracy in mixture genotyping. By sequencing each molecule within a sample for each marker of interest, the relative contributions of each individual within a mixture can be determined, allowing alleles to be more accurately assigned to a single contributor. However, at present these methods do not display the level of accuracy needed for forensic usage, and additionally require large quantities of DNA.

Conclusion

CE has become the predominant method of analysis within forensic biology, for several key reasons. The high level of resolution provided by entangled polymers provides sufficient resolution to genotype STRs and SNPs with high accuracy, while multicolor fluorescence detection permits highly multiplexed assays to be used. The introduction of high-throughput systems with multiple capillaries and rapid analysis times allows laboratories to keep pace with ever-increasing sample numbers, with automated systems decreasing analysts' input.

Future developments are likely to allow greater flexibility and ease-of use, as increasingly accurate portable CE systems are produced.

Introduction

The separation and quantification of chemical substances in a wide variety of complex matrices is a significant analytical challenge for the forensic chemist. While there is no doubt that capillary electrophoresis (CE) has had its largest impact in the area of forensic biology, specifically in the field of DNA analysis, it has also found application in forensic chemical analysis in general. Since the potential of CE for forensic analysis was first demonstrated in the early 1990s, it has been applied to a wide range of analytes of forensic interest including illicit drugs, toxicology samples, explosives residues, and pen ink.

CE is attractive for forensic applications because of its exceptional separating power (up to millions of theoretical plates), rapid analysis times, and high mass sensitivity (from femtomoles – 10^{-15} moles – down to yoctomoles – 10^{-21} moles). It is an economical technique in terms of reagents and consumables, requiring only minimal amounts of sample. Additionally, owing to the variety of separation modes possible (electrophoretic, electrokinetic, chromatography-like, etc.) and the detection systems available (UV–visible absorbance, luminescence, and mass spectrometry are all available commercially), it is applicable in the determination of a wide variety of chemical substances including inorganic ions, small organic molecules, chiral compounds, macromolecules, and intact viruses and cells. The Achilles heel of CE in the past has been its relatively poor detection limits when compared with liquid chromatography and gas chromatography (GC). However, improved detection optics and electronics for the most commonly encountered detector in CE, namely UV–visible absorbance, and the introduction of new detection techniques such as contactless conductivity detection have led to improved detection limits that are compatible with many forensic applications. Significant improvements in terms of sensitivity and specificity have been achieved in recent years by the hyphenation of CE with mass spectrometry (MS). CE–MS has become useful in clinical and forensic toxicology, doping control, and workplace drug testing, gaining attractiveness in respect to GC–MS and LC–MS.

The purpose of this article is to provide an overview of the application of CE to forensic analysis, illustrated with recent

examples. For more comprehensive treatments of specific areas, the reader is directed to the textbooks, monographs, and review articles listed in Further Reading.

Applications

Illicit Drug Analysis

CE has been used widely for the analysis of drugs and related compounds in pharmaceutical research and development since its introduction as a commercial analytical technique in the late 1980s. The potential of CE for forensic analytical problems was first demonstrated in the early 1990s with its application to the separation of illicit drugs in synthetic mixtures. Since that time, the determination of illicit drug seizures and clandestine lab materials has become a major application area for this group of techniques. Some examples of the application of CE techniques to such samples are presented on [Table 1](#).

In many instances, the choice of CE as an alternative technique to the more traditional GC and high-performance liquid chromatography (HPLC) methods is justified by the minimal amount of sample required and by the shorter and easier sample pretreatment. CE often allows for very short separation times, particularly when using techniques such as short-end injection are being used (see [Figure 1](#)). These features are beneficial to forensic analysis, particularly to screening for illicit drugs in clandestine preparations. In addition, CE lends itself to the difficult task of separations of enantiomers by the addition of a chiral selector to the background electrolyte (BGE). In addition to determining active illicit drugs, CE is also useful in separating cutting agents and other compounds that might be present, thus making it highly suitable for profiling type analyses.

Toxicology

CE has been successfully applied to a wide range of drugs, both therapeutic and illicit, and their metabolites in a wide range of biological matrices including urine, blood, and serum for forensic toxicological purposes.

Table 1 Applications of capillary electrophoresis to illicit drugs in seizures and toxicology samples

Analytes	Matrix	Method
Coca alkaloids and sugars	Illicit cocaine	MEKC with indirect UV detection
D-methamphetamine, L-methamphetamine, D-MDMA, L-MDMA, D-ketamine, L-ketamine, and heroin	Surfaces of banknotes, plastic bags, and silver paper	Liquid-phase microextraction followed by CZE using beta-cyclodextrin as a chiral selector, detection by UV absorbance
Heroin, morphine, acetylcodeine, caffeine, paracetamol	Heroin seizures	MEKC with short-end injection, detection by UV absorbance
Glucose, sucrose, lactose, mannitol	Heroin seizures	CZE with borate complexation and short-end injection, detection by UV absorbance
Codeine, ketamine, methamphetamine, morphine, alprazolam, and oxazepam	Urine	MEKC with UV absorbance detection
Methamphetamine, amphetamine, dimethylamphetamine, and <i>p</i> -hydroxymethamphetamine	Urine from subjects using methamphetamine and dimethylamphetamine	CZE using cyclodextrins for separation of enantiomers with MS detection
LSD	Blood	CZE with LIF detection
MDMA	Hair	CZE with UV absorbance detection

Figure 1 Electropherogram showing the separation of a seized heroin sample by using MEKC with short end injection (1) morphine, (2) heroin, (3) acetylcodeine, ISTD = internal standard (*N,N*-dimethyl-5-methoxytryptamine). UV absorbance at 210 nm, uncoated fused silica capillary 50 cm $\times$ 50 μ m I.D. $\times$ 360 μ m O.D., effective separation length 8 cm, back-ground electrolyte: 15 mM sodium borate, 25 mM sodium dodecylsulfate, 15% (v/v) acetonitrile, pH 9.5, 25 $^{\circ}$ C, -25 kV, hydrodynamic injection: 2 s at -50 mbar. CE has been applied to therapeutic drug monitoring, which has both clinical and forensic implications. Lithium salts are one of the most popular therapeutic approaches to the treatment of bipolar disorders, notwithstanding the introduction of modern, less toxic drugs. Because of its narrow therapeutic range, lithium serum concentration must be strictly monitored during the treatment to avoid life-threatening neurotoxicity. Capillary zone electrophoresis (CZE) was successfully applied to the routine determination of lithium in serum samples after a simple sample pretreatment of dilution with water and indirect detection using UV absorbance.

Small organic molecules, such as the central nervous system depressant and hypnotic gamma-hydroxybutyric acid (GHB), feature heavily as analytes in toxicological samples. GHB has been increasingly used as a recreational drug (owing to its euphoric effects and ability to reduce inhibitions) and as a rape facilitation drug. GHB has also been used as a doping agent for enhancing muscle growth. Analogs of GHB, namely gamma-butyrolactone and 1,4-butanediol, share its biological activity and are rapidly converted in vivo into GHB. CZE, in combination with UV detection, capillary electrophoresis-electrospray ionization-mass spectrometry (CE-ESI-MS), or conductivity detection, has been shown to be a rapid and accurate approach to the determination of GHB and its metabolites in urine and blood serum. Additional examples of illicit drugs determined in toxicological samples by CE are provided in [Table 1](#) with an example of analysis of hair for 3,4-methylenedioxymethamphetamine (MDMA) shown in [Figure 2](#).

CE can also be used for the determination of large biopolymers. It has been applied in the field of antidoping analysis to identify macromolecules. Recombinant human erythropoietin (rHuEPO) and the novel erythropoiesis-stimulating protein were analyzed by CE-ESI-MS using an ion trap mass spectrometry instrument as the analyzer. Additionally, affinity probe capillary electrophoresis/laser-induced fluorescence was developed for the detection of rHuEPO-alpha using a specific single-stranded DNA as aptamer probe. After optimization, the method was successfully applied for the quantification of rHuEPO-alpha in buffer, artificial urine, and human serum.

Toxins and venoms are products of living organisms, which in most cases have complex and unstable polypeptide structures. For these reasons, they are in general not suitable for GC analysis and are often 'difficult' to analyze with HPLC. CE provides an alternative approach for analyses of these challenging analytes. For example, the CE-ESI-MS method, using an ion-trap mass spectrometer, has been used for the identification of the biologically active oligopeptides of *Amanita* fungi, namely, alpha-, beta-, gamma-amanitin, phalloidin, and phalloidin. These complex analytes were also determined in real samples using a simple CZE separation with UV

Figure 2 Electropherogram of an extract from a sample of hair from a user of 'ecstasy' containing 3,4-methylenedioxymethamphetamine (MDMA) at a concentration of 4.0 ng mg^{-1} . Tetracaine and nalorphine were added as internal standards. Injection was by electromigration under field-amplified sample stacking conditions. Separation was by CZE using 100 mM phosphate pH 2.5 as the running buffer. Detection was by UV absorbance at 200 nm . Reprinted from Tagliaro F, Manetto G, Crivellente F, Scarcerella D, and Marigo M (1998) Hair analysis for abused drugs by capillary zone electrophoresis with field-amplified sample stacking. *Forensic Science International* 92: 20–211, with permission.

absorbance detection. Alpha- and beta-amanitin were determined in urine in less than 7 min with a simple sample treatment of dilution in BGE. Urine samples from suspected cases of intoxication with amanitins were analyzed, with beta-amanitin being identified in two samples.

Forensic Medicine

Recently, a number of protein molecules have become attractive as biological markers of chronic alcohol abuse. In particular, carbohydrate-deficient transferrin (CDT) has gained universal acceptance in this context, as reported in recent research papers and reviews. CDT is the collective name of a group of minor glycoforms of transferrin (the main iron transporting protein in human serum) with a low degree of glycosylation. CDT includes asialo-, monosialo-, and disialo-transferrin (Tf). CDT concentrations increase after sustained alcohol intake ($\geq 50\text{--}80 \text{ g day}^{-1}$), lasting for at least 7–10 days; there is a decrease after cessation of drinking with a half life of about 14 days.

CE was first applied to CDT analysis in the late 1990s and has since then rapidly gained acceptance. Today, together with HPLC, it is considered one of the most reliable analytical methods in the international literature. After the introduction of multicapillary instrumentation and ready-to-use commercial reagents, CE has become by far the most productive instrumental technique for CDT determination. Most CE methods are based on CZE separations using borate buffers added with organic amines (e.g., with diaminobutane, spermine, or diethylenetriamine) to hinder protein interactions with the capillary wall. Detection is based on absorption of UV radiation at $200\text{--}214\text{-nm}$ wavelengths. Examples of its application include CDT determination in blood microsamples collected from newborns using microhaematocrit tubes and analysis of cadaveric blood to study the postmortem stability and possible redistribution of CDT. Notwithstanding

a relevant haemolysis, CE separation allowed for CDT determination in 41% of the blood samples collected after death, showing an acceptable stability of the protein and the absence of an appreciable postmortem redistribution.

In a similar manner, changes in hemoglobin (HbA) induced by reaction with acetaldehyde, which is the first and most reactive metabolite of ethanol, has been proposed as a possible biomarker of alcohol abuse. A CE-ESI-MS method has been developed to study these adducts and applied to studies *in vitro*. When applied to real samples, this technique led to the identification of stable modifications of hemoglobin even in moderate alcohol drinkers.

Inks

Inks are complex mixtures of colorants, vehicles, and additives that are adjusted in composition to produce the desired writing characteristics. From a forensic point of view, ink analysis is mainly requested for ink-source comparisons, commonly conducted in casework involving such crimes as tax evasion, insurance fraud, and currency counterfeiting. The ability to distinguish different inks can be useful in criminal cases of document alteration, where two or more inks of the same apparent color, but with different dye compositions, were used in a document.

CE in common with other instrumental separation techniques, such as HPLC and GC, has been applied to the forensic analysis of pen ink. There are a number of reports in the literature, for example, of separations of water-soluble inks by CZE, using UV absorbance and laser-induced fluorescence detection. CE has also been used to analyze roller ball inks as part of ink aging investigation where the age of various ink samples was determined based on the relative quantities of components separated by CE.

The possibility of comparing inkjet printing inks by using micellar electrokinetic chromatography (MEKC) with diode array detection has also recently been proposed. The analytical procedure discriminated between the electrophoretic profiles of inks (extracted from paper) that were produced by five different manufacturers. The effective differentiation of individual inks was possible in terms of migration time, order, and specific shapes of characteristic peaks. The comparison of the recorded UV-Vis spectra also allowed for the identification of the main dyes.

Explosives and Gunshot Residues

Explosives have a long history of criminal use, and have become of increasing concern with their widespread use for international terrorism. The provision of information concerning the identity of an explosive at an early stage in an investigation is critical. Explosives and explosive residues can include a wide range of organic and inorganic components, thus necessitating an equally wide range of analytical techniques to identify them in the often complex matrix of postblast debris. Instrumental techniques, such as SEM-EDX, MS coupled with liquid or GC, x-ray spectrometry, infrared spectrometry, and ion chromatography, are used in combination with wet chemical tests (presumptive tests) to provide information on the identity and quantity of explosive residues.

Many organic and inorganic explosives and their residues are amenable to analysis by CE with acceptable limits of detection. CE is particularly well suited to the determination of inorganic ions that might be present in the postblast residue from improvised explosive devices (IEDs). In order to achieve the required level of confidence in identification of an explosive residue, corroboration through analysis by two independent techniques is required. In addition to the advantages of CE referred to earlier, the separation mechanisms in CE are substantially different from those of ion chromatography, thus providing a suitable orthogonal approach.

CE has also been shown to be useful in the separation and identification of components in gunshot residues (GSR). These residues are typically analyzed to identify persons who fired weapons and to investigate the sources and supply chains of ammunition. GSR analysis is traditionally based on the determination of heavy metals (usually lead, barium, and antimony) originating from the primer, but the production of 'metal-free' ammunition requires robust analytical methods for the identification of the organic components in the gunshot and explosive residues. Both the inorganic and organic components of GSR can be separated by CE simultaneously through the use of complexation for the metal ions and MEKC for the uncharged organic compounds (see Figure 3 and Table 2). The method was tested on real samples collected from weapons and from hands after firing.

Miniaturization

An area of significant recent research has been the move to develop portable instrumentation for at- or near-scene analysis. This is of particular importance for investigations involving clandestine drug laboratories and explosions. The National

Table 2 Characteristic organic and inorganic gunshot residue components listed with abbreviations used in Figure 3

Compound	Abbreviation	Usage
Nitroglycerin	NG	Propellant

stage of an investigation is extremely useful in rapid identification of potential suspects, in addition to being important for occupational health and safety reasons.

As described above, CE is well suited to the analysis of illicit drugs and explosives residues. However, commercially available benchtop instrumentation is too bulky to be used in the field. An area that shows great promise for forensic analysis is microfluidics, the so-called 'lab-on-a-chip.' Joseph Wang, one of the world's leaders in microfluidics, stated in a 2004 review that "microfluidic devices offer great promise for transporting the forensic laboratory to the sample source." Many microfluidic devices rely upon electrophoresis to separate analytes, with the advantage that miniaturization also leads to associated reductions in analysis times. For example, micro-chip capillary electrophoresis has been applied to the analysis of nitrate ester explosives, with ethylene glycol dinitrate, pentaerythritol tetranitrate, propylene glycol dinitrate, and nitroglycerin being separated in less than 3 min. Amphetamine, methamphetamine, and pseudoephedrine derivatized with a fluorescent label were separated by MEKC and quantified using a commercially available lab on a chip device intended for bioassays. The derivatization was achieved using a dry heating block procedure, which allowed for labeling of the drug analytes in 3 min and could feasibly be used in the field.

In addition to these lab-on-a-chip devices, other workers have focused on using shorter capillaries in combination with higher voltages to achieve rapid separations in portable instrumentation. These have required the development of novel flow-based sample introduction techniques. For example, a simple sequential injection capillary electrophoresis (SI-CE) instrument with contactless conductivity detection has been developed and applied to the determination of anions relevant to the identification of inorganic IEDs. The portable device was able to separate mixtures of key explosive tracer ions (nitrate, perchlorate, chlorate, and azide) in combination with common background ions (chloride, sulfate, thiocyanate, fluoride, phosphate, and carbonate) within 55 sections (see Figure 4).

Software control enabled a high analytical frequency of 60 samples per hour with high repeatability of separation times and detection limits in the $25\text{--}50 \mu\text{g l}^{-1}$ range. National Institute of Justice Guide for the Selection of Commercial Explosives Detection Systems for Law Enforcement Applications states that the nominal capability for explosive screening technology is that it "Can detect 100 μg of each target explosive in the swipe collection mode at least 95 percent of the time." For a typical ammonium nitrate-fuel oil explosive, 100 μg translates to approximately 73 μg of nitrate, which if dissolved in 1 ml of water, gives a concentration well above that of the detection limits for the SI-CE instrument.

Glossary

Analytes The analytes are the substances of interest that are being separated from the sample matrix by chromatography.
Chromatogram A chromatogram is a plot showing detector signal versus time; peaks are usually observed on the chromatogram when an analyte is emerging from the column.

Chromatograph A chromatograph is the instrument used to perform a chromatographic separation.

Eluate The eluate is the mobile phase leaving the column; it is usually monitored by some form of detection system.

Eluent The eluent is the solvent carrying the analyte through the stationary phase.

Abbreviations

GC Gas chromatography

HPLC High-performance liquid chromatography

SEC Size-exclusion chromatography

TLC Thin-layer chromatography

Introduction

In the majority of cases, samples encountered in the forensic science laboratory comprise a complex mixture of substances. Often, the forensic scientist is interested in looking at one or a number of these components (e.g., the level of a drug in a blood sample); however, there are very few analytical methods that are selective for a single chemical species. In reality, most compounds need to be relatively pure in order to identify them. Consequently, the analyte of interest must be separated from other compounds in the sample matrix in order to allow its identification and quantification. Chromatography is a powerful and versatile technique that is routinely used by forensic scientists for this purpose.

All chromatographic separations are based on the distribution of the sample components between two phases; the stationary phase and the mobile phase. The sample is dissolved in the mobile phase (which may be a liquid, solid, or supercritical fluid) and forced through an immiscible stationary phase. The stationary phase is generally solid particles or a viscous liquid fixed to the surface of a column or solid particles. On traveling through the stationary phase, molecules within the sample distribute themselves differently between the two phases. Molecules with a strong affinity for the stationary phase move slowly through the system. Conversely, molecules with a weak affinity for the stationary phase migrate very quickly through the system. This difference in migration rates allows the components to separate into discrete bands that can then be analyzed. A generalized schematic diagram showing a chromatographic separation is shown in [Figure 1](#).

Classification of Chromatographic Techniques

There are a multitude of different ways in which chromatographic separations can be performed. Consequently,

chromatographic methods are often classified into sub-categories. First, the physical setup of the stationary phase can be either planar or column based. In planar chromatography, the stationary phase is fixed onto a flat surface. Thin-layer chromatography is a good example of planar chromatography. Alternatively, column chromatography uses a column to house the stationary phase. Most chromatographic separations used in the forensic laboratory use some form of column chromatography. Second, the chromatographic technique is often classified according to the physical state of mobile phase (gas, liquid, or supercritical fluid) employed as the eluent. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) are commonly employed in the forensic laboratory, while supercritical fluid chromatography is less commonly found. In recent times, ultra-high-performance liquid chromatography (UHPLC) has emerged as a more powerful separation technique than HPLC offering reduced run times and increased separation power. UHPLC is increasingly being used in the forensic context.

Chromatographic techniques can be further subclassified upon the basis of the separation mechanism involved; these being adsorption, partition, ion exchange, size exclusion, and affinity. Liquid chromatography (LC) often employs separations based on an adsorption mechanism. In this case, molecules or ions adhere (adsorb) to the surface of the stationary phase (the adsorbent) via weak intermolecular forces. In general, the 'like dissolves like' principle can be applied. A nonpolar molecule will adsorb to a nonpolar stationary phase but will have little affinity for a polar stationary phase. Similarly, a polar molecule will adsorb to a polar surface but will be only weakly attracted to a nonpolar surface. Alternatively, most GC separations are based on a partition mechanism, whereby the molecules partition between two immiscible fluid phases. In GC, the stationary phase is most commonly a viscous liquid bonded to the interior of an open tubular column. The molecules being separated move in and

Figure 1 A diagram showing the principle of chromatographic separations. (a) a small volume of sample is placed at the top of the column which is filled with stationary phase and solvent. (b–d) Mobile phase is added to the top and allowed to slowly elute through the column, individual molecules interact with the stationary phase to different degrees and thus take differing times to move through the column.

out of this liquid in a mechanism analogous to a liquid–liquid extraction. A general schematic diagram showing adsorption and partition mechanisms is shown in [Figure 2](#).

Ion-exchange chromatography (often referred to as ion chromatography) allows the separation of ionic molecules on the basis of their charge. The surface of the stationary phase has ionic functional groups that bind to analyte molecules on the basis of coulombic (ionic) interactions. This type of chromatography is generally further subdivided into two groups: cation exchange chromatography and anion exchange chromatography. Cation exchange chromatography retains cations due to the negatively charged functional groups on the surface of the stationary phase. These can then be eluted from the column by introducing a competing cation such as H^+ to force the molecules back off the surface and into the mobile phase (thus exchanging places at the surface). Anion-exchange chromatography retains anions as a result of positively charged functional groups on the stationary-phase surface. In this case, the ions are eluted from the column by introducing a competing anion into the mobile phase, for example, hydroxide, which will exchange places with the bound anion. Generalized reaction schemes for the separation of ions by cation and anion exchange are shown below. In general, the higher the charge of the ion the greater the affinity for the charged stationary phase, the more slowly it will move through the system.

Figure 2 Schematic diagram showing the interaction of analyte molecules with the stationary phase (shown as a cross section). (a) An adsorption mechanism; analyte molecules are adsorbed directly to the stationary-phase surface and (b) a partition mechanism; analyte molecules are dissolved in a viscous liquid stationary phase bonded to the surface of a particle.

Size-exclusion chromatography is also known as gel permeation chromatography. As the name indicates, in this form of chromatography, molecules are separated on the basis of their molecular size. Molecules move through a porous stationary phase. Small molecules are able to move into the pores and become trapped, effectively removed from the bulk flow of the mobile phase. Larger molecules are unable to move into the pores and are washed around the stationary phase and elute quickly. The average residence time in the pores depends on the pore size of the stationary phase and the effective size of the analyte molecules ([Figure 3](#)).

LC methods are often subdivided into two further categories, those of normal-phase and reversed-phase chromatography. In normal-phase LC, the stationary phase is generally a polar solid such as silica or alumina, and the mobile phase is nonpolar. Historically, LC separations were generally performed using ‘normal-phase’ strategies. In the 1970s, nonpolar stationary phases were introduced for use with polar mobile phases such as water and methanol. These were termed reversed-phase systems. Reversed-phase systems based on an octadecyl carbon chain (C18) bonded to the surface of the stationary phase are the most commonly employed LC strategy in forensic laboratories.

As stated earlier, chromatographic separations are generally performed in some type of column setup. Column chromatography can be further subdivided into two types based on the type of column used: packed column chromatography and open tubular capillary column chromatography. Packed columns are filled with small particles that either serve as the stationary phase (adsorption chromatography) or serve as the support for a nonvolatile liquid coating which acts as the

Figure 3 Schematic diagram showing the interaction of analyte molecules with a porous stationary phase. As can be seen, small molecules move into the pores and are retained, while larger molecules are washed through.

stationary phase (partition chromatography). A variety of stationary phases is available. Packed columns are commonly used in LC. The use of packed columns in GC is relatively rare; however, they can be employed when increased sample capacity is required. Open tubular capillary chromatography is generally employed in GC and less commonly in LC. There are three types of open tubular columns. In wall-coated open tubular columns, the capillary wall serves as a support for a liquid film coating which acts as the stationary phase (partition chromatography). Support-coated open tubular columns contain solid microparticles that are coated with stationary phase fixed to the walls of the capillary (partition chromatograph). Finally, adsorption chromatography can be achieved using porous-layer open tubular columns, which have solid microparticles attached to the wall.

Chromatographic Distribution Equilibria

The effectiveness of a chromatographic separation depends in part on the distribution of the sample components between the stationary phase and the mobile phase. This distribution equilibria can generally be described as the transfer of the analyte (S) between the two phases. Therefore we can write

$$S_{(\text{mobile})} \rightleftharpoons S_{(\text{stationary})}$$

As with all equilibrium reactions, this reaction can be described by an equilibrium constant. In this case, it is known as the distribution constant (K_C):

$$K_C = \frac{[S]_{\text{stationary}}}{[S]_{\text{mobile}}}$$

The magnitude of the distribution constant is governed by the temperature, the type of compound, as well as the chemical composition of the stationary and mobile phases. Should these be kept constant, the separation will be able to be reliably

Figure 4 Example chromatogram showing the separation of two compounds. The first compound is unretained by the column and elutes at t_M , the second compound is retained from the column eluting later at t_R .

reproduced. Analytes with a large K_C will be more strongly retained by the stationary phase and thus take longer to elute from the column. If, under certain conditions, two analytes had the same K_C they would not be separable, a different set of chromatographic conditions would need to be used. By appropriate choice of the stationary and mobile-phase compositions, the distribution constants could be adjusted to allow their separation. In an ideal case, the K_C values for each analyte would be considerably different and all compounds within the mixture would be well separated.

Although the distribution constant is fundamental to chromatographic separations, it is not readily measured. Alternatively, analytes are usually monitored (using some type of detector) as they are eluted from a chromatography column. The result is a plot showing detector signal versus time, known as a chromatogram. **Figure 4** shows a typical chromatogram showing the chromatographic separation of two compounds. In this case, an unretained compound elutes first, followed by a compound that has been retained by the column.

As illustrated in **Figure 4**, the retention time (t_R) for each analyte is the time taken from injection of the sample mixture onto the column until the component reaches the detector. In many cases, a sample may contain species that are not retained by the stationary phase. These unretained compounds travel through the stationary phase in the minimum time possible. The time taken for an unretained peak to reach the detector is known as the void time (t_M). The void time provides a measure of the amount of time an analyte will spend moving in the mobile phase. The adjusted retention time is a measure of the time the analyte spends in/on the stationary phase. This can be measured by subtracting the void time (t_M) from the observed retention time (t_R) as shown below:

$$t'_R = t_R - t_M$$

The retention factor, k , is the ratio of the adjusted retention time (t'_R) to the void time (t_M) and is often used to compare the migration rates of analytes. That is because, for a fixed set of chromatographic conditions (stationary phase, mobile phase, and analyte) the value for k will be the same, regardless of flow rate:

$$k = \frac{t'_R}{t_M}$$

The retention factor can be related to the distribution coefficient (K_C) as it is effectively a measure of the time the analyte spends in each phase:

$$k = \frac{t'_R}{t'_M} = \frac{\text{time spent in stationary phase}}{\text{time spent in mobile phase}} = \frac{[S]_{\text{stationary}}}{[S]_{\text{mobile}}}$$

The separation factor, α , is a measure of the relative retention of two components and can be defined as the ratio of their two adjusted retention times:

$$\alpha = \frac{t'_{R_2}}{t'_{R_1}}$$

where $t'_{R_2} > t'_{R_1}$. Accordingly, the value for α is always >1 . In general, the greater the relative retention, the greater the separation between the components. Similarly to k , α is proportional to the ratio of the two analytes distribution coefficients.

Band Broadening in Chromatography

The efficiency of a chromatographic separation depends on two factors: (a) the difference in distribution coefficients as described earlier and (b) the broadness of the band of eluting analyte molecules. Band broadening results as analyte molecules traveling through the stationary phase tend to diffuse into a Gaussian-shaped band. Band broadening occurs to some extent in all chromatographic systems. In general, the wider the bands, the poorer the separation. Additionally, the longer the molecule spends on the stationary phase the broader the band becomes. This results in a broader peak on the chromatogram, and thus poorer separation efficiency.

The resolution, R_s , tells us how far apart two analyte peaks are relative to their widths and is defined as

$$R_s = \frac{2(t_{R_2} - t_{R_1})}{W_{b1} + W_{b2}} \\ = \frac{0.589(t_{R_2} - t_{R_1})}{W_{1/2 \text{ average}}}$$

where W_b is the peak width at baseline and $W_{1/2 \text{ average}}$ is the average peak width at half height as shown on the idealized Gaussian peak in [Figure 5](#). As shown below, separations where R_s values are <1.5 exhibit some overlap between the peaks. For quantitative analysis, a resolution of >1.5 is ideal.

Band broadening within the chromatographic system results from three different broadening processes namely, eddy diffusion (A), longitudinal diffusion (B), and interphase mass transfer (C). These processes are discussed separately, below.

A molecule (or ion) can travel throughout a packed stationary phase via a multitude of different pathways. As shown in [Figure 6\(a\)](#), the length of these pathways can differ significantly. As a result, analyte molecules may reach the detector over a time interval, leading to a broad peak. This broadening effect is termed eddy diffusion and is independent of mobile-phase velocity. Eddy diffusion (A) is related to average particle diameter (d_p) and packing geometry (λ) by

$$A = 2\lambda d_p$$

Eddy diffusion is minimized by using small uniform stationary-phase particles and tighter packing. Typical values are around 1.0 for a well-packed column.

[Figure 6\(b\)](#) illustrates the longitudinal diffusion of analyte molecules. Longitudinal diffusion describes the spread of analyte molecules or ions through random motion from regions of higher concentration to regions of lower concentration. Longitudinal diffusion (B) is related to the diffusion coefficient of the analyte in a given medium (D_M), an obstruction factor resulting from the packing (γ):

$$B = 2\gamma D_M$$

D_M is a function of both the analyte and the mobile phase, and γ is a constant that depends on the quality of the stationary-phase packing. Consequently, the magnitude of B can only be changed by varying the type, pressure, and/or flow rate of the mobile phase. Longitudinal diffusion is particularly important in GC and can be reduced by using high flow rates and/or denser gases. In LC, longitudinal diffusion is generally relatively small.

Broadening due to interphase mass transfer (C) results from the finite time taken for a molecule to equilibrate as it moves between the two phases. For packed columns interphase mass transfer is dependent on the diffusion coefficient (D_M) and the particle diameter (d_p) and is approximated by

$$C = \frac{1}{6} \frac{d_p^2}{D_M}$$

Interphase mass transfer is minimized by reducing the mobile-phase flow rate in order to allow the analyte molecules more time to equilibrate between the two phases. It is also minimized by using small particles, thin films of stationary phase, higher temperatures, and low-viscosity mobile phases. As a general rule, broadening in packed chromatography columns is most strongly influenced by the diameter of the stationary-phase particles. In contrast, the broadening in open tubular columns is influenced by column diameter, with reduced diameter resulting in decreased broadening.

These terms can be combined to determine column efficiency as defined by the height of a theoretical plate (H) and the linear mobile-phase velocity (u). This equation is known as the van Deemter equation and is generally applied in GC. Ideally, the value for H should be minimized to reduce band broadening and thus improve peak separation.

$$H = A + \frac{B}{u} + Cu$$

A representative van Deemter plot showing linear velocity versus H is shown in [Figure 7](#) below. As can be seen, the flow rate has significant impact on the overall efficiency of the chromatographic separation.

The term 'theoretical plate' is derived from distillation theory; in chromatography, the theoretical plate can be thought of as representing a single equilibrium step. The more theoretical plates (N) on a separation, the higher the efficiency of the separation. The number of theoretical plates is related to H and column length (L) via the following:

$$N = \frac{L}{H}$$

Figure 5 (a) Ideal Gaussian peak showing how W_b and $W_{1/2}$ are measured and (b–d) plots showing the effect of resolution of two individual peaks on the observed chromatogram. The solid line represents the observed signal, with the dashed lines representing the individual peaks.

Figure 6 Schematic diagram showing modes of broadening in chromatography. (a) Multiple pathways traveled by the analyte through a packed column (eddy diffusion) and (b) longitudinal diffusion.

N can be directly obtained from a chromatogram, the retention time of standard, and the peak width:

$$N = 16 \left(\frac{t_R}{W} \right)^2 = \frac{5.545 t_R^2}{W_{1/2}^2}$$

Additional Comments on Band Broadening

When open tubular columns are used in GC, the effect of eddy diffusion is removed due to the absence of packing materials and the modified Golay equation applies:

$$H = \frac{B}{u} + Cu$$

In HPLC, an additional mass transfer term needs to be incorporated to account for different mass transfer in each phase as described by the Huber equation, where C_s and C_m are the stationary-phase and mobile-mass transfer terms, respectively:

Figure 7 Exemplar van Deemter plot showing effect of flow rate on efficiency as measured by the height equivalent to a theoretical plate (H). Dotted lines show the contribution from the individual diffusion mechanisms.

$$H = A + \frac{B}{u} + C_s u + C_m u$$

In general, the eddy diffusion term and longitudinal diffusion term are very small when compared to the mass transfer

terms in HPLC, thus a reduced form of this equation is usually used:

$$H = C_s u + C_m u$$

Optimization of Chromatographic Performance

Chromatographic performance is optimized by varying experimental conditions until the components of a mixture are well separated. Consideration is often taken to the time frame of the separation. Optimization experiments are generally aimed at (1) adjusting the distribution equilibria of the analytes (thus changing the migration rates) or (2) reducing band broadening. Adjustments to the distribution equilibria can be achieved by changing the chemical composition of the mobile or stationary phase and adjusting the temperature. As described earlier, band broadening can be reduced by judicious choice of flow rate, minimizing particle or column diameter, and reducing film thickness.

Introduction

The complexity of real world sample matrices complicates the task of identifying and quantifying the presence of compounds of specific forensic interest. Gas chromatography (GC), along with other chromatographic techniques, is vitally important in forensic science to separate substances of analytical interest. GC is the primary technique for the analysis of fire residues. In the vast majority of cases, petroleum products are used as accelerants in fires and the peak patterns from the GC analysis can be used to identify the type of product (e.g., gasoline) that was employed in the fire. One of the earliest uses of GC in forensic science was in drug analysis. All sorts of 'street' drugs can be separated and quantified by GC. Blood and other body fluids are also analyzed for drugs and toxins by GC after suitable extraction processes have been carried out. The use of GC in the detection and quantitation of alcohol in drunk-driving cases is widespread. GC involves the use of a separation column, which is made from a length of glass, fused silica, or metal tubing. Like other forms of chromatography, a mobile phase flows through the separation column toward a detector. The mobile phase used in GC is an inert gas, such as nitrogen, helium, or hydrogen. The mobile phase is usually referred to as a carrier gas; when a mixture of substances is injected at the column inlet, each component is *carried* toward the detector by the mobile *carrier gas*.

To be amenable to analysis by GC, compounds must have a relatively high vapor pressure. Many compounds can be analyzed in their native form, while many others need to be chemically derivatized to make them sufficiently volatile, less polar, and/or more thermally stable. For separation to occur, the GC column must contain a stationary phase. The stationary phase may be a solid or a liquid. Depending on whether the stationary phase is a solid or a liquid at its operating temperature, GC is classified as gas-solid chromatography (GSC) or gas-liquid chromatography (GLC). Retention in GSC is based mainly on differences between the adsorption affinities of the sample components for the surface of an active solid. Although GSC predates GLC, the use of GLC is far more prevalent and it is common to drop the 'L' and refer to this technique simply as GC. In GLC, a viscous polymer is coated as a thin film either directly on the inside wall of the tubing (wall-coated open tubular (WCOT) column) or onto a solid support material,

which is packed tightly into the separation column (packed column). Separation occurs because sample components partition between the stationary phase and the mobile phase (carrier gas) according to the equilibrium expression called the distribution constant (K):

$$K = \frac{C_S}{C_M} \quad [1]$$

where C_S and C_M are equilibrium concentrations of the solute in the stationary phase and the mobile phase, respectively.

The distribution constant depends on the strength of the intermolecular forces between the solute and the surface of the stationary phase. A sample component with a large distribution constant will be more strongly retained in the stationary phase than a sample component with a small distribution constant, so the former will take longer to pass through the separation column to the detector than the latter. This time is called the retention time (t_R) and is characteristic of the chemical properties of the solute and the stationary phase. Like all chemical equilibria, K is highly dependent on temperature, so retention time is temperature dependent. The relationship between K and t_R is shown in eqn [2]:

$$K = k\beta \quad [2]$$

where the retention factor $k = (t_R/t_M) - 1$ and the phase ratio $\beta = (r_c - 2d_f)/2d_f \cong r_c/2d_f$ for WCOT columns. t_M represents the gas hold-up time (the time required for a nonretained substance – e.g., the mobile phase – to transit the column), r_c is the inside radius of the capillary GC column, and d_f is the thickness of the stationary phase film.

Operation of a gas chromatograph may be performed using a set temperature (isothermal analysis), or by systematically increasing the temperature during the analysis (temperature-programmed analysis). For a particular application, it is generally recommended to operate the gas chromatograph at the lowest temperature compatible with a reasonable analysis time.

GC Columns

The column is the heart of a GC system. GC columns fall into three distinct categories: packed GC columns, porous layer

open tubular (PLOT) GC columns, and WCOT CG columns. The latter are typically on the order of 100–530 μm internal diameter and are generally available in 5–100 m lengths. Contemporary packed GC columns are typically 2–5 m long and usually have an internal diameter of 1–2 mm, although micro-packed GC columns with smaller internal diameters have recently become increasingly popular. PLOT GC column dimensions are similar to WCOT GC column dimensions.

WCOT GC columns are favored by GC users for their high separation efficiency and are often simply known as capillary GC columns due to their ubiquity. Capillary GC columns are typically made of fused silica and are extremely rugged when an external coating of polyimide polymer is applied. The approximate operating temperature range of fused silica GC columns is -60 – 350 $^{\circ}\text{C}$, depending on the type of stationary phase coating. High-temperature capillary GC columns made from specially deactivated metal tubing are suitable for operation in excess of 400 $^{\circ}\text{C}$.

There are four main measures of the success of a GC approach: efficiency, selectivity, speed, and sensitivity. *Efficiency* is the ability of the approach to separate analytes as sharp, compact bands, which in turn means that more analytes can be separated in a single analysis. That is, the peak capacity increases as efficiency increases. Selectivity is the ability of the separation approach to discriminate between analytes and is most evident in the sequence in which analytes emerge from the GC column. *Sensitivity* is the ability of the separation approach to detect very low concentrations of analytes. Efficiency and selectivity are perhaps the most important attributes because they will ultimately determine whether the analyte(s) of interest can be separated. The length and internal diameter of the capillary GC column as well as the chemical composition and thickness of the liquid stationary phase coating are important variables that affect each of these four measures of success of a GC approach.

For thin film (or more specifically, high β) GC columns, *efficiency* (N) is related to column length (L) and internal diameter (d_c) by

$$N \approx \frac{L}{d_c} \quad [3]$$

Although separation efficiency is inversely proportional to column internal diameter, narrow-bore columns suffer from reduced sample capacity. When sample capacity is exceeded, the column becomes overloaded, leading to peak-broadening and reduced efficiency. Table 1 lists some typical capillary GC column diameters and provides some insight into the suggested use of these columns. For samples with a variation in solute concentration, a low β column is recommended to reduce the possibility of broad overloaded peaks coeluting with target analytes. For low β columns, the simplified equation for estimating column efficiency (eqn [3]) does not apply because resistance to mass transfer in the thick liquid stationary phase becomes a significant factor that reduces efficiency, when compared to a high β column. Thick film columns lead to increased retention when compared to thin film columns. Since this increases elution temperature, low β columns are particularly suitable for analyzing volatile compounds. Thin films are generally better suited for high-molecular-weight compounds.

Table 1 Common capillary GC column diameters and suggested uses

Internal diameter (μm)	$N\text{ m}^{-1}$	Uses
100–150 (narrow-bore)	10 000–6700	Fast GC columns producing narrow peaks
220–250	4500–4000	Ideal for GC-MS and high-resolution analysis
320	3100	Good resolution and good sample capacity. Good range of detector compatibility
530 (wide-bore)	1900	Large sample capacity and good ruggedness; higher flow rates required mean that these columns are usually not suitable for MS

Stationary phase selection has considerable impact on *selectivity*. The separation of two solutes is dependent on the ratio of vapor pressures and the ratio of activity coefficients (solute/stationary phase intermolecular forces). When choosing a capillary GC column, conventional wisdom recommends selecting the least-polar stationary phase that will perform the required separation. The retention mechanism in ‘nonpolar’ GC columns, such as polydimethylsiloxane, is largely correlated with analyte vapor pressure. When using ‘polar’ GC columns, activity coefficients bear more influence on retention. For instance, increasing the amount of phenyl and/or cyano-propyl content in the stationary phase leads to separation being influenced by differences in dipole moments or charge distributions. By way of further example, stationary phases containing polyethylene glycol lead to separation being influenced by hydrogen bonding; thus, this type of stationary phase column is widely used for separation of compounds such as aldehydes and alcohols. In general, nonpolar compounds chromatograph best on nonpolar phases, and polar compounds on polar phases, but this is not necessarily the decisive factor.

Speed is often confused with analysis time. Analysis time is measured as a function of the retention time of the last peak, the cool-down time between analyses, and any sample preparation steps, while speed relates to the number of peaks per unit time produced in a chromatogram. Readers should consult the ‘Further Reading’ section for excellent discussions of fast GC.

Sensitivity arises from a combination of the type of detector employed, the sample-introduction method, chromatograph settings, and cleanliness. The inertness of the chromatographic system, including the GC column, is of critical import for the sensitive detection of some classes of compounds. The technology of producing capillary GC columns of controlled internal diameter and stationary film thickness is considerably advanced. Commercially available WCOT columns with a variety of polymer stationary phases have a consistently high efficiency, exhibit ever-improving inertness, and give excellent analytical results.

Packed columns do not possess the high efficiency and separating capability of WCOT columns, but they do have

Table 2 Types of analyses in which GSC is applied

Type of adsorption material	Targets
Alumina	C1–C5 hydrocarbons
Carbon	CO and CO ₂ in air
Molecular sieves	Permanent gases, O ₂ , CO, N ₂ O in blood
Porous polymers	Volatile polar and nonpolar compounds; samples containing water, solvents
Silica	C1–C3 hydrocarbons, samples containing water

high sample capacity. This simplifies sample introduction and provides a larger quantity of sample component for introduction to the detector. Typical packed columns for analytical work are 2–5 m in length and have an internal diameter of 1–2 mm and use carrier gas flows of 20–50 ml min⁻¹. Micro-packed GC columns of smaller internal diameters have become popular for specific applications, but packed column GC has essentially been replaced by capillary GC. Short capillary GC columns (2–5 m) can provide the same efficiency as a packed column, but achieve equivalent results in substantially less time. Specialty capillary GC columns for specific assays, such as blood–alcohol analysis, which were once performed almost exclusively using packed column GC, are readily available from multiple vendors.

Packed columns for GSC predate those for GLC, and despite many literature methods being described these columns were somewhat maligned. Contemporary PLOT columns offer superior separation characteristics for GSC, compared to packed-GSC columns. A list of common GSC solid support materials is provided in Table 2 along with types of analyses in which GSC is applied in forensic science.

Gas Pressure and Flow Control

The most common carrier gases for GC are N₂, He, and H₂. The main difference of these gases is the different effect they have on diffusion constants. Carrier gas viscosity is sometimes a secondary concern. Contemporary gas chromatographs are fitted with electronic pressure control to provide sufficiently accurate pneumatic conditions required for highly reproducible GC analysis. Separation speed and efficiency are dependent on the volumetric flow rate of the carrier gas. The high popularity of capillary GC has led to detailed studies of efficiency optimization. Efficiency in capillary GC is intrinsically linked to the carrier gas volumetric flow rate. The carrier gas volumetric flow rate at the column outlet ($F_{c(o)}$) can be measured directly using a flow-meter, or calculated using eqn [4]:

$$F_{c(o)} = \left[\frac{60\pi r_c^4}{16\eta L} \right] \left[\frac{(p_i^2 - p_o^2)}{p_o} \right] \quad [4]$$

where η is the dynamic viscosity of the carrier gas at the operating temperature, L is the column length, and p_i and p_o are the column inlet and outlet pressures, respectively.

Two generalized optimal carrier gas flow rates have been determined: (i) a speed-optimized flow rate ($F_{\min Q}$); the shortest analysis time for a column of given efficiency and diameter can be achieved by using $F_{\min Q}$ and (ii) an efficiency

Table 3 Recommended speed-optimized flow rates for capillary GC columns

	Hydrogen (ml min ⁻¹)	Helium (ml min ⁻¹)	Nitrogen (ml min ⁻¹)
$F_{\min Q}$ for 100 μ m column	1.0	0.8	0.25

Flow rates measured at 25 °C and 1 atm.

optimized flow rate ($F_{\min H}$) that leads to maximum in N . The two optima relate as:

$$F_{\min Q} = \sqrt{2} F_{\min H} \quad [5]$$

The speed-optimized flow rate does not depend on the column length, the film thickness, or the pressure drop. It depends only slightly on column temperature, so it has been recommended as a default flow rate for capillary GC. Table 3 shows the values of the speed-optimized flow rates for a 100 μ m internal diameter column. These flow rates can be generalized by using the following simple formula:

$$F_{\min Q} = F_{\min Q, 100 \mu\text{m}} \left[\frac{\text{column diameter } (\mu\text{m})}{100} \right] \quad [6]$$

Oven Temperature

For a particular separation, the lowest temperature compatible with a reasonable analysis time should be used. If the time is excessive, it is generally better to reduce the stationary phase loading than to increase the column temperature.

In a screening procedure for complex mixtures with components of widely varying retention characteristics, it may be very difficult or impractical to select a column temperature that will allow all the components to be resolved. It is, therefore, necessary to vary the column temperature throughout the analysis, starting with a low temperature and finishing with a higher value. Peak capacity is affected by increasing the gradient of the temperature program, and excessively fast temperature programs are generally avoided except for very short columns, operated at a very high carrier gas flow rate. Too-rapid temperature programming causes a mismatch between the plate duration and temperature increase. To this end, the same authors who uncovered the optimal pneumatic conditions discussed previously proposed a generally accepted optimal temperature programmed gradient of 10 °C/ t_M . This rule of thumb is an excellent tool for those developing new approaches.

There is a maximum temperature at which a column can be operated, and there is also a minimum temperature below which the efficiency will drop sharply. In GLC, the stationary phase must be a liquid at the temperature of operation, and if a column is operated at too low a temperature the stationary phase may still be in the solid or semisolid form.

Sample Introduction

Sample introduction in GC is critical. The sample must be introduced to the head of the column as a narrow band or

else resolution will be reduced. The composition of the injected plug should be truly representative of the original mixture to avoid affecting the quality of quantitative results. A range of injectors exists to permit the introduction of a wide range of samples. Correct choice of injection mode and proper technique are of critical importance for obtaining high-quality GC analysis results.

Split/Splitless Injection

The most common injection technique is liquid injection through a self-sealing septum into a heated split/splitless injection port. The liquid sample solution is vaporized in the heated port. For split injection only a small part of the vapor enters the column, with the remainder being vented to waste. Split injection should be used for concentrated liquid samples, and is also used for gas and headspace analysis. The flow rate up to the split point is high, so the injection port is emptied quickly. The primary advantage of split injection is that narrow injection bands are introduced to the capillary GC column. Split injection is ideal for high-resolution and fast-GC separations. By sending most of the sample to waste, split injection is not suitable for trace analysis. Splitting sometimes causes discrimination against high-molecular-weight solutes in the sample so that the sample entering the column may not be representative of the sample injected.

In forensic analysis, more components are present at trace levels, particularly in alternative matrices such as hair, saliva, or sweat, and target substances may be undetected because most of the sample is vented to the atmosphere and does not reach the detector. For analysis of trace compounds, the splitless injection technique is generally used. Splitless injection offers improved sensitivity over split injection. Nearly all the sample vapor is transferred from the injector port into the column. Splitless injection is performed with a split injector and requires careful optimization for good results. The top of the column is held at a low temperature to condense the sample contained in the solvent. Without reconcentration, the volume of the injection region will increase the bandwidths of eluting peaks and reduce the efficiency of the separation.

One method of reconcentration is known as the solvent effect. This occurs because the front of the solvent plug that enters the column mixes with the stationary phase and is more strongly retained than the rear of the solvent plug. Sample components, therefore, encounter a barrier, which has the effect of condensing components at the head of the column. This applies only to compounds with a boiling point near those of the solvent. When a solvent starts to volatilize, compounds with a similar boiling point are concentrated. It is preferable to choose solvents with low volatility (i.e., hexane, toluene, and octane). For example, the use of toluene for amphetamine and isooctane for cannabinoids is recommended. Because of the interaction of the solvent and the stationary phase, some columns can be damaged if polar or aromatic solvents are used. To accomplish this solvent effect, it is necessary that the column temperature at injection is low enough to prevent the solvent from migrating too rapidly from the head of the column. This requires a column temperature of 20–40 °C below the boiling point of the solvent, and may require auxiliary cooling of the oven. A second means of

solute reconcentration is cold trapping. In this method, the initial column temperature must be about 150 °C below the boiling points of the components to be trapped. Compounds with lower boiling points require a solvent effect for reconcentration.

With the split valve closed, carrier gas flow through the injector port is slow. Thus, the time to sweep all the solvent vapor on to the column is sufficient to cause a large solvent tail, which interferes with early eluting peaks. Therefore, after a specified time (split valve off-time), the operation of a solenoid valve causes conditions to change so that the inlet flow is greater than the column flow, which remains constant. Any solvent or sample remaining in the injector is vented with carrier gas.

On-Column Injection

The injection modes previously described all require flash vaporization of the sample, sometimes leading to sample discrimination or decomposition of thermally labile compounds like lormetazepam or lorazepam, two benzodiazepines. These can be overcome by injecting the sample directly into the WCOT column, or directly into a capillary precolumn through a cool injection port (at the same temperature as the column). This method of injection for WCOT columns (internal diameter 0.25–0.35 mm) was not prominent among early injector designs, owing to the mechanical difficulties of aligning the syringe needle with the column. Like splitless injection, on-column operation requires cold trapping or the solvent effect to concentrate the sample at the head of the column. On-column injection syringes have needles which are too fine to penetrate a septum and, in order to minimize carrier gas loss, valve assemblies are used which grip the needle or which only open when the needle is in the narrow entrance channel.

Solid Injection

Solid injection is used when solvent interference is serious. The 'moving needle' injector has found application in steroid analysis and for the determination of anticonvulsant drugs. A solution of the material to be injected is placed on the tip of the glass needle with a syringe. A small flow of carrier gas sweeps the solvent out of the top of the device to waste. The dry residue is then introduced by moving the needle into the heated injection zone of the chromatograph with a magnet. This form of injection can only be used with drugs that will not volatilize with the solvent.

Programmed Temperature Volatilization Injection

The programmed temperature volatilization (PTV) mode of injection exhibits the advantages of split-splitless and on-column injectors. The sample is introduced in a cold vaporization chamber to avoid sample degradation and loss of compounds. The injector is warmed slowly to evaporate the solvent and to concentrate the sample (there is the possibility of concentration without the conventional extraction step with an organic phase and concentration by evaporation). The injector is then heated rapidly and split or splitless injection is operated. Degradation of analytes is

minor and comparable with the on-column injection technique.

Headspace Introduction

Headspace analysis permits the detection of volatile substances in a liquid or solid sample and minimizes column contamination. A small volume of the sample is placed in a vial sealed with a septum and the sample vial is equilibrated at an appropriate elevated temperature. A sample of the vapor is removed with a syringe and is then injected using one of the previously described techniques. This technique is used extensively in the assay of ethanol and other solvents in blood and for complex household preparations, such as polishes, which contain volatile substances.

In forensic toxicology, biological fluids are easily and directly analyzed (without sample preparation), but tissue such as lung (identification of abused volatile substances), intestines (to determine the method of administration), and muscles may also be analyzed. Muscles are used to confirm carbon dioxide intoxication when biological fluids, and particularly blood, are not available at autopsy (for instance, if the body has been dried by the high temperature of a fire). Methyl and ethyl mercaptans are used to document alkane intoxication (methane, propane, and butane). After fatal massive ingestion of ethanol, ketones from an overloaded liver metabolism may be identified (i.e., isopropanol and acetone).

Pyrolysis GC

There are many complex substances of forensic interest that do not have sufficient vapor pressure at the normal operating temperatures of the gas chromatograph. These include hairs and fibers, paints, plastics, adhesives, and other substances that are polymeric in nature. The technique of pyrolysis GC can be conveniently used to characterize these substances. This technique is very sensitive to minute differences in the chemical content of such materials, and is quite reproducible, thus aiding in comparisons of known and unknown samples.

Pyrolysis injectors are heated under controlled conditions to temperatures exceeding 1000 °C after the sample is introduced. Since the injector and interface are continuously bathed

by an inert carrier gas, the analyte does not burn (no oxygen available). Instead, it thermally decomposes into simpler molecules. If the pyrolysis is performed under constant conditions and the sample size and topography are similar each time, then the resultant pyrogram will be quite reproducible with respect to the number and relative abundance of the fragmentation.

Simple Injection – Dual Detection

Simple injection followed by dual detection is possible by placing a tee-piece or γ -connector between the retention gap and two different analytical columns, which are each coupled to a detector. It is also common to connect two columns directly to the injector by way of a ferrule drilled with two holes. The dual detection approach is highly popular because primary and confirmatory analyses can be performed with a single injection.

Figure 1 shows a dual-detection GC analysis of blood alcohols by capillary GC with two detectors. This technique can also be used to analyze the large family of psychotropes (benzodiazepines, tricyclic antidepressants, neuroleptics, etc.).

Detectors

In GC, the detection problem is that of sensing a small quantity of organic compound in an inert carrier gas. To detect these compounds under such a wide variety of conditions, a number of detectors have been developed. The ideal detector will have high sensitivity, wide linear dynamic range, and a small cell volume so that the GC peak is not distorted. Those in most common use in forensic science are the flame ionization detector (FID) and electron capture detector (ECD), and mass spectrometry (MS).

Flame Ionization Detector

An FID is among the most commonly used detectors; it is unresponsive to air, water, carbon dioxide, ammonia, hydrogen sulfide, sulfur dioxide, and most GC carrier gases, but responds readily to compounds containing carbon and hydrogen. Cations and electrons are produced when the effluent of a GC column containing vapors of organic substances is combusted

Figure 1 Baseline resolution of blood alcohols in less than three minutes on dual capillary columns. Primary and confirmation analyses can be done from a single injection by using a two-hole ferrule. Reproduced from Restek Clinical/Forensic Products (2007) Lit. Cat.# 580156. Bellefonte: Restek Corporation, with permission of Restek Corporation.

in a hydrogen/air flame. A collector electrode is used to collect the created ions and produce a small current. The electrical conductivity of the flame is very sensitive to the presence of organic vapors and an FID can respond to approximately 20 pg of each component eluting from a capillary GC column.

Nitrogen–Phosphorus Detector or Alkali FID

The introduction of alkali metal vapors into the flame of a FID confers an enhanced response to compounds containing phosphorus and nitrogen. Modern versions of this detector have an electrically heated rubidium silicate source of metal ions. The detector is particularly useful for drug analysis because most drugs contain nitrogen, while the solvent and the bulk of the coextracted material from a biological sample do not. This detector is also especially useful for the detection of pesticides containing phosphorus.

Electron Capture Detector

From the time of its discovery, the ECD has seen a steady growth in development and use. This is a selective detector, which is highly sensitive to all electron-reacting compounds containing halogen, nitro group, or carbonyl group (i.e., benzodiazepines, pesticides, halogenated solvents, and anesthetic gases). The detector consisted of a small chamber with two electrodes parallel to each other and a radioactive source, usually ^{63}Ni , placed close to the cathode to ionize the carrier gas. A potential applied to the electrodes produces a steady background current. Compounds with a strong electron affinity, such as halogenated compounds, capture electrons and reduce the background current. ECD has exceptional sensitivity and is capable of detecting femtogram quantities of compounds such as carbon tetrachloride. Because the ECD response comes about from a loss of signal rather than an increase in signal, ECD can easily be overloaded (the signal cannot drop below zero). Typically, the dynamic range of ECD is on the order of about 10^4 .

Mass Selective Detector

Generally, the courts of justice recognize chemical analysis results only in cases where they can be verified by a second independent method such as gas chromatography-mass spectrometry (GC-MS). A mass spectrometer is especially well suited as a detector for GC. The main requirements of a mass spectrometer are to (i) produce gas-phase molecules, (ii) ionize these gas-phase molecules, (iii) separate the ions formed, and (iv) detect and record the separated ions.

In GC, the sample is vaporized when it is injected into the column (or shortly afterward if we use cool-on-column injection) and exits the column as gas-phase molecules, so the first requirement is already fulfilled. In GC-MS, a heated transfer line between the GC and the MS is essentially all that is required. The mass spectrometer needs to be operated under high vacuum to increase the mean-free distance that ions are able to travel. If the vacuum is not maintained, the mean-free distance is reduced because the ions might collide with other molecules before they reach the detector. If this happens, sensitivity is sacrificed. Capillary columns are ideally suited to

GC-MS analysis because the typical carrier gas flow rates are $<2\text{ ml min}^{-1}$ and the MS vacuum system can easily deal with this rate of delivery of carrier gas into the ion source.

Ion formation is critical in any MS approach. In GC-MS, the most common approach is electron impact ionization (EI). EI is a hard ionization approach, which will ionize every compound eluted from the GC column. EI produces reliable mass spectra; distinct fragmentation patterns for organic compounds are produced, and it is possible to elucidate structural information from the spectra, either from first principles, or by performing a library search using a database of reference spectra. A disadvantage of EI includes a reduced abundance of the molecular ion. If the molecular ion is desired, then chemical ionization (CI) is used because it is a soft ionization approach, in which molecular ions or 'quasimolecular ions' are produced and fragmentation is kept to a minimum. In a CI interface, the sample is mixed with a large excess of a reagent gas, such as methane, ammonia, or isobutane. The mixture is then passed through a beam of high-energy electrons, as in EI. The reagent gas undergoes preferential ionization and the primary ions so produced react with further reagent gas molecules. These secondary ions subsequently react with the sample molecules to produce new ions. Usually, few fragmentation/rearrangement ions are observed and this quasimolecular ion is the most intense ion in the spectrum. EI and CI are complementary techniques, thus providing both molecular weight and fragmentation information. The majority of the work done has involved the study of positive ions, but interest in the negative chemical ionization (NCI) technique has increased in recent years. For example, the CI mode of detection for negative ions is the technique of choice for detecting benzodiazepines because they possess halogen groups located on aromatic rings with high negative density that will give more stability to the anions formed in the ion source.

Potential instrument problems can arise when fast-GC is used, since the peaks can be very narrow. In this situation, the mass spectrometer must have a sufficiently fast spectral acquisition capability to detect the peaks. Some time-of-flight mass spectrometers (TOFMSs) are suited to fast-GC because their acquisition rate can be as high as $1000\text{ spectra s}^{-1}$. Quadrupole mass analyzers are not capable of such high data acquisition rates and are more suited to conventional speed GC separations, although in recent times quadrupole mass analyzers have become faster with up to $20\,000\text{ amu s}^{-1}$ reported.

Hyphenation of GC with tandem mass spectrometry (MS/MS) is a specialized form of GC-MS. The simplest MS/MS instrument is a triple-quadrupole mass spectrometer. Here, two quadrupole mass analyzers are combined with a multipole collision cell. Separation occurs in the first mass analyzer in the conventional way, except that only selected ions are allowed to pass to the collision cell, where the precursor ions are fragmented to form product ions. Following separation of the produced daughter ions in the second mass analyzer, a highly informative mass spectrum is produced. Multiple reaction monitoring is a related approach that increases the specificity of an analysis. For targeted analysis, known precursor ions are selected in the first mass analyzer, and the second mass analyzer is set to monitor only selected product ions. New triple-quadrupole mass spectrometers permit femtogram-level determination for targeted GC-MS/MS analysis.

HPLC High-performance liquid chromatography

TLC Thin-layer chromatography

Introduction

Liquid chromatography is a broad classification used to describe a variety of different chromatographic configurations that rely on the use of a liquid mobile phase. Paper, thin-layer, and classical column chromatography techniques, as well as high-performance liquid chromatography (HPLC) and ion chromatography, all belong to the class of liquid chromatography. These techniques are heavily used in forensic science to separate a wide range of analytes including, but not restricted to, illicit drugs, drugs, and drug metabolites in toxicology samples, explosives residues, and textile fiber dyes. A variety of separation mechanisms can be used within liquid chromatography; these include adsorption, ion-exchange, size-exclusion, affinity, and ion-pair formation. A discussion of these separation mechanisms can be found in *Chromatography: Basic Principles*. This article gives an overview of classical, high-performance, and thin-layer chromatographic techniques including experimental configurations and forensic applications.

Column (or Liquid–Solid) Chromatography

- Column chromatography is commonly used in sample purification and cleanup, particularly in synthetic organic laboratories. One of the simplest chromatographic techniques to set up, column chromatography utilizes commonly available laboratory materials to effect the separation. The column typically comprises either a laboratory pipette or a burette that is filled with a solid stationary phase (typically alumina, silica, or celite). The mixture to be separated is dissolved in an appropriate solvent and added to the top of the column. Mobile phase is continually added to the top of the column and liquid flow is continued through the column. Compounds are separated on the basis of their differential migration through the column. Compounds with a strong affinity for the stationary phase take a longer time to be eluted. The eluted compounds can be collected, recovered, and examined.

In the 1960s and 1970s, toxicologists routinely used column chromatography for the isolation and purification of drugs and pesticides from biological fluids. More recently, commercially prepared ‘solid-phase extraction’ (SPE) chromatography columns have become the most commonly used column chromatography system for sample cleanup in the

forensic laboratory. Ready to use SPE columns of varying stationary phase composition can be purchased from a variety of chromatographic suppliers. The choice of stationary phase is dependent on the analyte of interest, with SPE columns suitable for proteins, drugs, and pesticides being readily available.

HPLC and Ultrahigh-Performance Liquid Chromatography

In order for a sample to be successfully analyzed by gas chromatography (GC), it must be volatile (vapor pressure at least 1 torr) and stable in the vapor phase at elevated temperatures. Many organic compounds, such as drugs and explosives, do not fit this criteria. For such compounds, HPLC is a viable alternative as it is applicable to a much greater range of compounds than GC. In theory, any compound that can be dissolved is able to be separated by HPLC. There are some limitations, however; appropriate mobile and stationary phases must be available, the compounds must be stable in the solvent system, and suitable detection systems must be at hand. Overall, HPLC is an extremely powerful separation technique that is widely used in all areas of analytical science.

HPLC is an extension of column chromatography, and typically uses a stationary phase that has a very small particle size (typically 3–5 μm in diameter) that has been tightly packed into a commercially produced column (generally 3–25 cm in length and 3–5 mm internal diameter). Samples (generally 1–20 μl) are introduced into the column via an injection port. The decreased particle size (compared with classic column chromatography) results in increased contact between stationary phase and the mobile phase and superior resolution to classical column chromatography. A consequence of the decreased particle size and tight packing is that the flow of mobile phase through such a tightly packed column is highly restricted. Therefore, a quality pump capable of sustaining high inlet pressures (up to 400 bar) is employed to propel the mobile phase through the column. Thus, HPLC is often termed ‘high-pressure’ LC. Typical mobile phase flow rates range from 0.3 ml min^{-1} to 1.0 ml min^{-1} . The outlet of the HPLC column is generally coupled to a flow through detection system such that the eluted compounds can be directly detected as they leave the column, without need for further modification. A number of different approaches can be used to detect the eluting analytes, the most common ones being ultraviolet–visible (UV–vis) absorbance spectrophotometry and mass spectrometry (MS). The resulting separation is

Figure 1 Schematic diagram of the components of an HPLC System, Inj = sample injector.

recorded as a graph of detector response versus time, which is referred to as a chromatogram. Modern HPLC instrumentation is typically fully automated with computer control of the pump, injection, and detector components. The schematic diagram in **Figure 1** shows a typical instrumental setup.

It is well documented in HPLC that decreasing the stationary phase particle size results in improved separation efficiency. However, until recently, the use of smaller particles had been limited as the pressure required for percolating the mobile phase through a column packed with smaller particles was prohibitive using conventional HPLC systems. Over the last decade, ultra-high-pressure liquid chromatography (UHPLC) instrumentation comprising a combination of innovative reduced particle size solid phase supports capable of withstanding higher pressures and advanced pumping systems able to deliver the mobile phase at these higher pressures (can be up to 1200 bar) has become a commercial reality. Both HPLC and UHPLC operate on the same principles; however, UHPLC offers superior performance with regard to speed and resolution. The use of UHPLC has been reported to decrease run times by a factor of 10 without loss of resolution. Furthermore, the incorporation of longer UHPLC columns can increase resolution of poorly resolved analytes while maintaining an acceptable analytical time frame, and achieve greater detection sensitivity.

One of the reasons for the success of HPLC (and UHPLC) as a technique is its flexibility. A wide range of stationary phases is available to the analyst. These are typically of silica or polymeric makeup and are specifically designed to withstand the high pressures within the column. These stationary phases can be used in combination with an almost limitless range of mobile phase compositions to achieve very high degrees of separation efficiencies. HPLC (and UHPLC) can be run in either normal phase (stationary phase more polar than mobile phase) or reversed phase (stationary phase less polar than mobile phase) mode. In reversed phase chromatography, the polar compounds elute first from the column, whereas in normal phase chromatography, nonpolar compounds are the first to elute.

A variety of different separation mechanisms are used in HPLC (and UHPLC), the most common being partition. Further detail regarding the separation mechanisms used in chromatography can be found in *Chromatography: Basic Principles*. A number of variables can be changed in order to improve separations through HPLC (and UHPLC). Most commonly, the mobile phase composition is altered. This can be achieved either by preparing a new mobile phase off-line or by using modern pumps that are able to mix the solvent online. Furthermore, with the use of modern pumps, chromatographers

are able to alter the mobile phase composition during a run (gradient elution). Most forensic separations rely on the use of reversed phase chromatography with mobile phases comprising a mixture of an aqueous buffer and an organic solvent. Special care needs to be taken with selecting the mobile phase as small changes in pH and solvent content can result in markedly different separations. In addition to the mobile phase composition, column flow rates and temperature can also be varied in order to effect a separation. If these measures prove unsuccessful, an alternate stationary phase should be considered.

Many molecules exhibit UV-vis absorption, and as a consequence, UV-vis detection is by far the most commonly used detection method coupled with HPLC. (For a detailed discussion of UV-vis spectroscopy, see other articles in this encyclopedia). These detectors are generally set at a fixed (programmable) wavelength. Alternatively, diode array detectors are often coupled to the HPLC system, and these allow the collection of the UV-vis spectrum of the eluting compound. Diode array spectra are useful in that they can be used to compare with known compounds using a library search as well as to evaluate the purity of the eluting compounds. For those molecules that do not exhibit a chromophore in the UV-vis region, alternative detection systems are required. A differential refractive index detector compares the refractive index of the eluting compounds with that of the mobile phase. While widely applicable, this detector is generally not suitable for gradient elution as the mobile phase composition (and thus the refractive index) changes throughout the run. Fluorescence detectors can offer a sensitive detection system; however, the use of this detector requires that the compounds of interest are naturally fluorescent or can be made to fluoresce by chemical derivatization. In evaporative light scattering detection (ELSD), the column eluent is merged with a gas and atomized into small droplets. The mobile phase is allowed to evaporate, leaving fine particles suspended in the gas. These particles scatter light, and the magnitude of the scattering is measured. Theoretically, the detector responds to nonvolatile substances and the response should be proportional to the mass of solute present. MS is emerging as the HPLC detection system of choice in forensic laboratories as it gives structural as well as quantitative information about the compounds eluting from the HPLC column. There are many ways in which LC can be interfaced with MS, and as such the reader is referred to other articles in this encyclopedia.

HPLC has been applied to a wide variety of forensic applications. Examples include the analysis of ball point inks from documents, condom lubricants, explosive residues, and hemoglobin in blood. The most common forensic application of

Figure 2 Separation of 35 benzodiazepine and other drug standards by HPLC coupled with mass spectrometric detection.

HPLC, however, is in the analysis of drugs and toxins. Over the last 10 years, HPLC (especially when combined with MS) has become the method of choice for the analysis of nonvolatile drugs that are difficult to analyze using GC. An example of where HPLC is particularly useful is in the analysis of benzodiazepines. Benzodiazepines are commonly prescribed drugs and can be subject to misuse. As a result, they are commonly tested for as a part of forensic toxicological screening. An example chromatogram given (Figure 2) below shows the separation of 35 different benzodiazepine and other drug standards that is achieved using HPLC coupled with MS.

Thin-Layer Chromatography

Thin-layer chromatography (TLC) is a variant of liquid chromatography, with the mobile phases and stationary phases utilized being common to both. However, in TLC, the stationary phase is present as a thin layer upon a planar inert rigid support, rather than as a column. This approach was first proposed in the 1930s, but TLC, in the form it is used today, was not established until 1950s. Today, there is a wide range of premade plates with a variety of different stationary phases available to the scientist. A typical TLC separation involves application of a solution of the sample to be analyzed as a discrete spot or smear upon the chromatographic plate. Once the solvent in which the sample was applied has evaporated, the plate is developed by allowing a mobile phase to move by capillary action through the stationary phase, carrying the components contained within the sample with it. These components are retained to different extents by the stationary phase, thus leading to separation.

There are some key differences between TLC and HPLC. In TLC, unlike HPLC, there is no need for the sample solvent to be compatible with the mobile phase as it is evaporated off when applying the sample to the plate. Similarly, there is no requirement for the mobile phase to be compatible with detection as is the case with HPLC. TLC is an 'open-bed' method, with retention being observable at all stages, unlike in HPLC where if a component is strongly retained, the only indication will be the lack of a peak. In TLC, standards and samples can be run simultaneously on a single plate under identical conditions. A key advantage of TLC is its relative simplicity when

compared to other chromatographic techniques. The steps in a TLC analysis have been defined as follows:

1. Selection of a suitable chromatographic stationary phase
2. Application of the sample
3. Selection of a mobile phase
4. Development
5. Visualization and detection

This can also be followed by quantification, by removing the spot of eluted material and extracting into appropriate solvent before subsequent analysis with some other instrumental technique.

There are, however, some disadvantages to TLC. Owing to the reliance on capillary action for development, the flow rate of the mobile phase is difficult to control with any precision. Detection limits are also an issue, with HPLC being far better in this regard. In addition, there is a certain amount of manual dexterity required to load (or 'spot') the samples onto the plate and this can introduce some variability.

A range of stationary phases are available for TLC, which can be classified on the basis of their composition and primary mechanism of retention. The most popular phases in common use are silica gel and alumina, the main retention mechanism for both being due to an adsorption process involving affinity of polar and polarizable compounds to the stationary phase. Nonpolar components are not retained and move further along the TLC plate. Aromatic compounds are readily polarizable; hence, this mode of TLC is well suited, for example, to the separation of fiber dyes that have extensive aromaticity and many other polarizable functional groups.

The stationary phase is laid down as a thin layer (100–2000 μm thick) upon an inert rigid support, glass or aluminum. While in earlier times the scientist had to undertake the laborious and time-consuming process of preparing these plates from scratch, there are now many commercial sources of premade plates. Before use, plates need to be stored and prepared in a controlled and reproducible manner, preferably in a humidity-controlled environment to ensure reliable results.

Appropriate application of the sample is highly important for obtaining good separations. In principle, it is very simple; using a glass capillary or micropipette, the dye extract is applied as a spot approximately 2 mm in diameter, typically about

1 cm from the bottom edge of the plate. To ensure good results, there are a number of practical issues that need to be faced. Care needs to be taken not to damage the adsorbent layer or to produce an excessive spot size. The solvent used to load the sample should be able to wet the stationary phase and it should also be volatile so that it can be driven off before the development of the plate. This process can be accelerated through the application of heat, either applied using a hair dryer or by having the plate rest upon a hot surface. To increase the amount of analyte material on the plate, thereby providing a more detectable result, repeated application of sample on the initial spot could be carried out. It is recommended that both questioned samples, and known samples or standard mixtures are run at the same time, with the questioned sample being bracketed by known samples or standards. The applied spots should not be too close to each other, or to the edge of the plate.

There are a number of different approaches to developing TLC plates, with varying levels of complexity. However, the simplest and most widely used approach is the ascending linear method. Once the plate is completely dry, it is placed in a pool of eluent contained within a covered chamber. The eluent used will depend on the stationary phase and the analytes being separated and typically consists of mixtures of various solvents in different proportions, providing different degrees of polarity. Issues that need to be considered when deciding whether a particular eluent system is suitable for a particular analyte mixture include separation and sharpness of bands, the distance the bands have moved from the origin, and the proximity of the solvent front and the concentration of the analytes within the mixture to the separated bands. The development chamber can be as simple as a beaker with a Petri dish cover or, alternatively, a commercially available development chamber. Before use, the eluent needs to stand for a few minutes in the covered chamber to allow the chamber to become saturated with eluent vapor. The depth of eluent should be such that when the plate is placed in the chamber, the eluent level should be below the applied spots; a distance of at least 0.5 cm has been recommended. The eluent will then move up the plate by capillary action; this process takes only a few minutes and separation of the components within the applied dye spots will be observed. Development should be carried out until the eluent has traveled around 2 cm beyond the origin where the spots were applied. Any further than this may lead to the separated spots become diffuse, which makes visualization and interpretation problematic.

Interpretation of the developed TLC plates is carried out by comparing the band position and colors of the questioned and known (standard) components. This can be done under normal laboratory lighting if the analytes are colored (e.g., fiber dyes) or with the use of UV light. Commercially available TLC plates contain a UV fluorescent dye, so separated analyte bands will appear as dark spots against a bright background. A visualizing reagent that reacts with the separated analytes to provide a colored spot may be used; for example, ninhydrin was used to detect amino acids separated by TLC before its application as a latent fingerprint detection reagent. The elution characteristics of compounds can be reported as R_f values, which are a measure of the relative distance traveled by each

Figure 3 Schematic diagram illustrating the measurement of R_f values for a TLC separation.

compound from the origin with respect to the solvent front (see Figure 2).

However, care must be taken when comparing between plates because of subtle differences in development that lead to different retentions (Figure 3).

TLC has found application in forensic testing in areas as diverse as illicit drugs, explosive residues, and particularly, textile dye analysis.

Introduction

One of the analytical challenges posed by forensic science includes the identification and quantification of complex mixtures containing known, unknown, and suspect compounds within complex matrices. Ultra- and high-performance liquid chromatography (UPLC and HPLC) coupled with soft ionization techniques (e.g., electrospray ionization (ESI) or atmospheric pressure chemical ionization; APCI), along with low-resolution (triple quadrupoles and ion trap) and high-resolution (e.g., quadrupole-time of flight, Orbitrap, and Fourier transform ion cyclotron resonance) mass spectrometers, have significantly progressed the molecular-level characterization of complex drugs, metabolites, macromolecules, and synthetic chemicals. In the past, gas chromatography (GC) coupled with mass spectrometry (MS) was recognized as one of the primary analytical techniques used in forensic laboratories. GC–MS was widely used for analysis of illegal substances in body fluids, testing fibers and blood from a crime scene, and detection of explosive residues. However, GC–MS-based techniques often require extensive sample cleanup and, for the analysis of polar compounds, the routine application of derivatization procedures. These limitations have been overcome by the advent of LC–MS-based techniques. Moreover, the urgency in developing fast and reliable analytical methods with minimal sample preparation has driven solid-phase extraction (SPE) media and column manufacturers to offer a new means of rapidly and effectively cleaning up and injecting samples into mass spectrometers. Ionization

sources, sample preparation techniques, emerging injection methods, matrix effects, and state-of-the-art LC–MS instrumentation are critically discussed in the following sections, along with the examples of applications to forensic science taken from the scientific literature. Throughout this article, HPLC is used interchangeably with LC.

Ionization Techniques

In the early 1970s, the introduction of samples into mass spectrometers was ‘the issue’ limiting the development of reliable LC–MS systems. The challenge originated from the difficulty to (1) introduce a sample at atmospheric pressure (760 Torr) into a low-vacuum region ($<10^{-6}$ Torr) without disrupting the vacuum and (2) efficiently convert a liquid mobile phase into a spray of charged ions. The invention of the ‘thermospray’ source along with the introduction of innovative MS designs, including multiple vacuum stages independently pumped, was what made LC and MS finally come together.

Nowadays, at the forefront of available ionization techniques, ESI is by far the most widely used ionization source. This is followed by an APCI source. Electrospray ionization takes place as a result of imparting a strong electrical charge (kV) to the mobile phase emerging from the nebulizer. The spray of charged droplets undergoes size reduction by solvent evaporation. When the droplets have a sufficient charge density, sample ions are ejected from the surface of the droplets.

This phenomenon is known as ‘ion evaporation’ or ‘Columbian explosion.’ The main drawback of ESI is that the analytes can ionize in solution with multiple charge (e.g., doubly charged ions will appear in the MS spectra at $m/2z$). Moreover, ESI and other atmospheric pressure ionization (API) techniques suffer from ‘ion suppression’ or ‘matrix effects,’ which often limits their direct applicability for quantitative assessment.

APCI produces protonated or deprotonated molecular ions by transferring (in positive mode) or abstracting (in negative mode) a proton from the molecule. The liquid sample coming from the HPLC is vaporized in a heated nebulizer, and it emerges in a plasma made of solvent ions formed within the atmospheric source by corona discharge. The corona discharge produces reactant ions, such as N_2^{o+} and N_4^{o+} , by electron ionization. These ions collide with the vaporized solvent molecules to form other reactant gas ions (e.g., H_3O^+ and $(H_2O)_nH^+$), which undergo repeated collisions with the analyte forming analyte ions. APCI is best suited for analysis of nonpolar and semi-polar compounds. Both ESI and APCI provide a ‘soft’ ionization of chemicals, allowing direct mass measurement of thermolabile and polar compounds, while minimizing ‘in source’ fragmentation.

The atmospheric pressure photo-ionization (APPI) source was introduced in early 2000. APPI allows ionization of nonpolar and semi-polar compounds, which usually are poorly ionized under ESI and/or APCI ionization conditions. The APPI source uses a krypton lamp, which emits photons at a specific wavelength, to optimize analyte ionization, while reducing in-source ionization of air and other common HPLC solvents (e.g., methanol and acetonitrile).

New generation ambient ionization methods that have been introduced since 2004 are the DART (direct analysis in real time), DESI (desorption electrospray ionization), and ASAP (atmospheric solids analysis probe) sources. Apart from their smart acronyms, each of these ambient ionization methods utilizes a plasma to ionize sample molecules or use molecules in the atmosphere, which then proceed to ionize the sample. The minimal sample preparation required for ambient ionization is very important to drastically reduce the analysis time. DART, DESI, and ASAP have numerous applications in which real-time ‘chemical fingerprinting’ is required, or where ESI, APCI, and APPI are not effective in ionizing the compounds of interest. Ambient ionization techniques are useful to perform real-time analysis of surfaces, coatings, and materials, analysis of biological samples, in situ histological identification of tissues, food control analysis, drug discovery, pharmaceutical quality assessment, and counterfeit drugs. There are also numerous forensic applications, including the analysis of porous surfaces (e.g., paper) and postmortem analysis of amines from mammalian decomposition fluid or tissues.

Matrix-assisted laser desorption/ionization (MALDI) is a soft ionization technique for the analysis of biomolecules, biopolymers, and in general large organic molecules (e.g., DNA, RNA, proteins, sugars, lipids, oligosaccharides, bacteria, phosphopeptides, and synthetic polymers). Although the real mechanism of MALDI is still under debate, the process includes: (1) matrix material desorption triggered by a UV laser beam followed by (2) analyte ionization occurring in the hot plume formed during the ablation process of the upper layer of the highly UV absorbing matrix material.

Variations of MALDI includes SELDI (surface-enhanced laser desorption ionization), SALDI (surface-assisted laser desorption/ionization), DIOS (desorption ionization on porous silica), and SEND (surface-enhanced neat desorption) among others. For example, SELDI is mostly used to analyze proteins in tissue samples, urine, blood, body fluids, or other clinical samples.

Sample Preparation and Injection Techniques

To concentrate and cleanup samples for injection into LC–MS systems, off-line SPE is by far the most used sample preparation technique. SPE typically is performed with sample volumes ranging from milliliters to liters. Samples are loaded onto a preconditioned stationary phase, where analytes are retained based on their polarity or their acidic or basic properties. Cartridges are then washed, and analytes are eluted with excess solvent removed by evaporation. The most common SPE media commercially available include C8–C18 end-capped silica (for hydrophobic interactions), polymeric stationary phases (for hydrophilic/hydrophobic interactions), and mixed mode cationic and anionic resins (for hydrophilic/hydrophobic/ion-exchange interactions). SPE is widely used to extract, concentrate, and cleanup samples, but it is possibly the most ‘time-consuming’ and therefore, expensive means of sample pretreatment. The major costs include the labor required to perform SPE, including method development, purchasing the SPE cartridges, that typically are used once and then disposed solvent usage and disposal, and the large volume of samples to be shipped. If SPE is performed on a stand-alone apparatus (SPE manifold + vacuum pump) or by online SPE instruments (automated SPE extractor), laboratories incur additional costs to purchase such equipment and to optimize, operate, and maintain SPE instrumentation.

Online SPE has been gaining importance in the last decade, as it combines recovery and cleanup typical of ‘off-line SPE’ with minimal sample handling (e.g., centrifugation or filtration), allowing fast and relatively cheap high throughput of samples. However, online SPE requires purchasing of expensive instrumentation such as online SPE cartridges and pre-columns, and possibly a second HPLC pump along with multipoint valves for high-pressure applications.

Direct injection (DI) and large volume injection (LVI) sample injection techniques are performed simply by introducing crude samples straight into an analytical column followed by spectroscopic and/or spectrometric detection. DI usually employs small volumes (i.e., few microliters) of sample and is recommended when analytes are present at high concentrations in the matrix. LVI instead uses high sample volumes (i.e., 100–5000 μ L) for analysis of chemicals present at low concentrations in the matrix. Compared to other techniques requiring extensive sample pretreatment, DI and LVI are easier to set up, only requiring small hardware modifications to existing auto-samplers (e.g., LVI may only require a possible increase in loop size and/or upgraded analytical head). As for online SPE, with DI and LVI, tunable gradients can be set up to achieve ‘on-column’ cleanup, while injection valves (usually mounted on most mass spectrometers) can be used to divert unwanted chromatographic slices to waste. Given that sample handling/

pretreatment is usually the ‘rate-determining step’ of sample throughput in analytical chemistry, LVI and DI represent valid and cheap alternatives to both off-line and online SPE. Method development and validation, as well as routine analyses are faster and cheaper with DI and LVI, as they reduce sample handling and material involved to a minimum. In the last decade, LVI and DI techniques have been increasingly gaining acceptance among analytical chemists. These sample injection approaches are emerging as analytical tools which will possibly render SPE redundant for a number of analytical applications.

Matrix Effects

Analytes ionized by API sources are affected by matrix effects, which are responsible for suppressing and, less frequently, for enhancing their absolute response. This often results in variable detection limits and more importantly, in inaccurate quantitative results. The matrix effect was first reported by Tang and Kerbarle back in the early 1990s, where they observed that the detection capability, precision, and resolution in ESI were influenced by coeluting interferences. The matrix effect originates in the early stages of the ionization process, and is usually expressed as:

$$\text{Matrix effect (\%)} = 100 \times (A_s - A_m)/A_s$$

where A_s and A_m are the area of the analyte in the standard solution and in the matrix, respectively. It has been reported that matrix components are thought to suppress the analyte response mainly by (1) changing viscosity and surface tension of mobile-phase spray, causing reduced evaporation efficiency, (2) competing with the analyte to gain or lose a charge, therefore limiting the ejection of ions from the charged spray, and (3) neutralization in gas phase via deprotonation reactions with high gas-phase basicity compounds using APCI. Different approaches have been proposed to compensate for matrix effects. These include (1) calibration methods (e.g., inclusion of deuterated homologs and standard addition method), (2) dilution of sample extracts (e.g., with LC mobile phase), (3) injection of reduced volumes (few microliters rather than tens of microliters), (4) specific sample preparation strategies (e.g., off-line and online SPE, protein precipitation), (5) improvement of chromatographic selectivity (e.g., employing different mobile-phase compositions and elution gradients), and (6) ‘echo-peak’ technique.

By far, the most reliable and effective method to account for the matrix effect is the inclusion of deuterated homologs, as the analyte and the coeluting deuterated standard would be subject to almost identical matrix effects. However, deuterated homologs are quite expensive and are not always commercially available, which can limit their possible inclusion in an analytical assay. The second calibration method is the ‘standard addition method,’ which consists of analyzing the original sample followed by the same sample containing known amounts of an added standard. This calibration technique has proven to be effective to correct for matrix effects. Autosamplers can be programmed to accurately perform online multiple spiking of the original sample, making the standard addition method more accessible and less time-consuming.

Methods utilizing dilution of sample extracts and/or injection of reduced volumes aim to introduce less matrix into the API interface so that the resulting ionization of analytes is more efficient. The downside of this approach is that the analytes of interest are often at low concentration levels, so dilution of a sample extract or injection of a reduced sample volume also results in a lower absolute amount of analyte entering the mass spectrometer.

Both off-line and online SPE can be used to reduce the matrix effect mainly by selective extraction, inclusion of a ‘washing step,’ and selective elution. For example, to extract an acidic drug with a positively charged mix mode anion exchange resin, the sample pH should be buffered two pH units above the pK_a of the acidic analyte to ensure the analyte is fully deprotonated. After extraction, a washing step with water and methanol is typically applied to selectively elute basic and neutral interferences from the stationary phase. Analyte elution is then performed using mixtures of basic methanol and acetonitrile. Similarly, with online SPE, it is possible to selectively extract and elute analytes, as well as add a washing step by eluting a weak elution strength mobile phase through the online SPE cartridge.

Protein precipitation is used to reduce the matrix effect in biological fluid analyses; however, different problems arise, such as incomplete protein precipitation, low analyte recoveries, and dilution of the final extract, thereby making SPE a better choice.

Changing the mobile-phase composition and elution gradient can improve the selectivity of the separation and is also an effective way to reduce the matrix effect. The two chromatographic areas to avoid are the solvent front, where polar unretained organic and inorganic species elute, and the end of the chromatographic run, where highly retained hydrophobic interfering compounds elute.

The ‘echo-peak’ technique, proposed recently, involves injection of an analytical standard followed by injection of the sample extract, so that analytes in the standard and in the sample are eluting in a ‘similar chromatographic region’ and therefore should be subject to a similar matrix effect.

Although it has been proven that matrix effects are compound and sample dependent, investigations on how the analyte response is affected by matrix components should be taken into consideration during the development and validation of new analytical methods. Understanding how matrix effects qualitatively and quantitatively affect analytical results is recognized as an important step toward ‘good laboratory practices.’

Overview of State-of-the-Art LC–MS Instrumentation

The most commonly used instruments in laboratories around the world are triple quadrupoles (QqQ) and quadrupole ion traps (Q-ITs). QqQs are known as ‘transmitting instruments,’ as the front (Q1) and end (Q3) quadrupoles are set to allow only certain m/z values or ranges to be transmitted for detection. QqQs also feature a collision cell (q), usually full of argon for fragmentation. Beside different acquisition modes, including MS scan, daughter scan, parent scan, neutral loss, and MS survey scan, QqQs feature the multiple reaction

monitoring (MRM) data acquisition mode. In the MRM mode, a parent ion is selected in the first quadrupole, fragmented in the collision cell (q) and two (or more) formed daughter ions are selected in the third quadrupole. In MRM, one parent → daughter transition is used for quantitative assessment, while the second transition is used to confirm the presence of a certain chemical species in the sample. Monitoring the retention time along with the measured MRM ratio in both the sample and the calibration curve generally confirms detection. Sensitivity and selectivity make QqQ the instrument of choice to quantify low picogram–femtogram levels of known compounds in a variety of complex matrices.

Q-ITs are known as ‘trapping instruments,’ as they use constant direct current and radio frequency oscillating electric fields to trap ions. The strength of these systems is that they allow data acquisition in the selected reaction monitoring (SRM) mode, increasing the specificity of detection of known molecules while offering high sensitivity and selectivity with low risk of false positives. Q-IT can be also operated in MS/MS or MS^n ($n=2-10$) mode allowing, to some extent, structural elucidation of unknowns. Screening information-dependent acquisition is also used with Q-IT systems, where an automated switching between MS and MS/MS during a scan is triggered on the basis of certain threshold criteria. Both QqQ and Q-IT are generally operated at unit mass resolution, limiting their effectiveness for structural elucidation.

High-end MS systems combine high-resolution and high-resolution capabilities with the diagnostic feature of fragmentation (MS/MS and MS^n). So-called hybrid systems can comprise a combination of a quadrupole and a time of flight (Q-TOF) or a Q-IT coupled to a high-precision electrostatic ion trap (Q-IT-Orbitrap). Q-TOFs usually present a front quadrupole (Q) for parent ion selection, followed by a collision cell, in which ions are fragmented before being subjected to accurate mass analysis in a TOF mass spectrometer. TOF works by accelerating ions to the same kinetic energy. The time the ions take to travel through a defined path length is measured, and this information is used to calculate the mass-to-charge ratio for each ion. Q-TOFs are usually operated at 15 000 resolving power in ‘sensitivity mode,’ or at 30 000 resolving power in ‘mass resolution’ mode. The latest generation Q-TOFs, introduced in late 2010 by AB Sciex, feature 40 GHz, four-channel time-to-digital converter (TDC) and detector, enabling unprecedented speed acquisition rates (e.g., 100 scans per second with ‘MRM like’ sensitivity in MS mode and up to 50 scans per second in MS/Ms mode) with high resolving power even in the low mass range. This allows for fast screening, identification, and quantitation on known, suspect, and unknown compounds in a few seconds. Given the fast scan rate of Q-TOF technologies, the inclusion of an UPLC for faster and more efficient chromatography is certainly an option to be considered to increase sample throughput. Recent developments in ion mobility separation (IMS) technology have enabled coupling to Q-TOF MS by Waters. The inclusion of a high-resolution traveling wave IMS cell allows ions to be separated on the basis of size and shape, as well as mass-to-charge ratio before being introduced in the mass analyzer.

The other class of hybrid instruments are based on the patented ‘Orbitrap’ technology. These instruments, built by Thermo-Fisher Scientific, combine a Q-IT with a high-precision

ion trap (Orbitrap). Orbitrap measures the oscillation of ions back and forth within an electrostatic field. A Fourier transform mathematical operation is then used to convert those frequencies to a mass spectrum. Q-IT can be operated as a mass analyzer independent from the Orbitrap, or as an ion storage and injection system for the Orbitrap mass analyzer. The Q-IT can be operated in full scan, single ion monitoring (SIM), MS/MS product ions, MS^n ($n=2-10$), and SRM. The Orbitrap allows resolving power up to 100 000 at $m/z=400$, with mass resolution less than 3 ppm with external calibration. The main strength of this hybrid system is that it allows multiple scan modes, multiple collision cells, multiple dissociation methods, multiple mass analyzers, and multiple detectors for MS^M experiments. For example, in the ‘dual detection’ mode, low-resolution MS/MS or MS^n data can be acquired in the Q-IT, while at the same time high resolution (e.g., 100 000) and high mass resolution (<2 ppm, with internal calibration) MS data are acquired in the Orbitrap over the same analytical run. The main downside of the Q-IT Orbitrap is that MS resolution depends on the scan rate. The relatively slow scan rate of the Orbitrap at high resolving power somehow limits the applicability of this technology to fast UPLC separation. Nevertheless, Q-IT Orbitrap along with Q-TOF technologies offers unparalleled levels of structural elucidation though high resolution and high mass resolution fragmentation experiments.

Fourier Transform Ion cyclotron resonance mass spectrometers (FT-ICR-MSs) are the current pinnacle of MS performance. This type of mass analyzer is used to determine the mass-to-charge ratio (m/z) of ions based on the cyclotron frequency of the ions in a fixed magnetic field. FT-ICR-MS combines ultra-high resolving power ($\sim 1\,000\,000$) and very high mass accuracy (<1 ppm) along with various fragmentation techniques, achieving unprecedented characterization of unknown polar compounds in complex mixtures. FT-ICR generally offers 10–100 times higher mass resolution and mass accuracy than other mass analysis techniques, allowing direct determination of elemental composition ($C_xH_yO_zN_r \dots$) and molecular structure even without prior chromatographic separation (i.e., through direct infusion in ESI). Owing to the mass defect of the elements, FT-ICR is especially useful to study the molecular composition of large multiple charged biomolecules in complex mixtures. Forensic applications of FT-ICR are various and include the direct determination of ignitable liquids in criminal investigations of suspected arson fires. The drawback of both FT techniques (i.e., ICR and Orbitrap) is that the resolving power comes at the expense of scan speed. FT-ICR systems are also very expensive to purchase and operate, and this limits their widespread application in analytical laboratories. The main characteristics of the MS technologies described in this section are summarized in Table 1.

The values reported for resolving power, mass accuracy, sensitivity, dynamic range, and scan speed can vary from one MS manufacturer to another, and they should be considered as a broad guide only.

Application of LC–MS to Forensic Sciences

HPLC coupled with tandem MS has become the technique of choice for the analysis of pharmaceutical samples and

Table 1 Resolving power, mass accuracy, sensitivity, linear dynamic range, scan speed, strength, and weakness of various commercially available MS spectrometers

Mass spectrometer	Resolving power (mass/FWHM) ^a	Mass accuracy (ppm) ^b	Sensitivity	Linear dynamic range	Scan speed ^c	Strength	Weakness
QqQ	Up to 5000 ^d	~5–50	fg–pg (SRM, MRM)	10 ⁴ –10 ⁶	Up to 15 000 Da/s	-Reliable for quantitation -MRM data acquisition -Low risk of false positives -HPLC/UPLC ready	-Limited diagnostic power because of low sensitivity in MS scan -Limited resolution and MS accuracy
Q-IT	Up to 10 000	~5–50	fg–pg (SRM, MS Scan)	10 ³ –10 ⁴	Up to 66 700 Da/s	-Relatively cheap -Reliable for quantitation in SRM -Good diagnostic power in MS^g -Information-dependent acquisition data -HPLC/UPLC ready -Relatively cheap	-Resolution depends on scan rate -Limited MS accuracy/resolution
Q-TOF	Up to 40 000 at $m/z \sim 300$	<3 ^e <2 ^f	fg–pg (MS scan)	10 ² –10 ⁴	100 Hz in MS scan and 50–100 Hz in MS/MS at 30 000 resolving power	-Fast scan rate -Good diagnostic power because of HR MS/MS capability -Good MS accuracy -Unlimited m/z range -HPLC/UPLC ready	-Resolution depends on m/z range and decreases at low m/z -High sensitivity or high-resolution modes are possible but not simultaneously -Loss of sensitivity moving to HR -Expensive -Daily MS calibration required
Q-IT Orbitrap	Up to 100 000 at $m/z \sim 400$	<3 ^e <2 ^f	fg–pg (MS scan)	10 ⁴	1 Hz at m/z 400 and 100 000 resolving power ^g	-High diagnostic power because of HR MS/MS and MS^g capability -Information-dependent acquisition data -Very good MS resolution and accuracy -Dual detections on IT/FTIR -MS^M capable	-Resolution depends on scan rate -Limited m/z range (50–4000) -HPLC only is recommended for most applications -Expensive
FT-ICR	Up to 1 000 000 at $m/z \sim 400$	<1	Low fg–pg (MS scan)	10 ⁴		-MS calibration done weekly -Ultimate diagnostic power because of ultra HR MS/MS capability -Very high MS resolution and accuracy	-Very expensive to purchase, operate, and maintain

QqQ: triple quadrupole MS; Q-IT: 2D linear ion trap MS; Q-TOF: quadrupole-time of flight MS; Q-IT Orbitrap: 2D linear ion trap Orbitrap MS; FT-ICR: Fourier Transform Ion Cyclotron Resonance MS; HR: high resolution.

^aMass resolution indicates the ability to discriminate two ions with an m/z difference of Δm ; resolving power is measured as the observed m/z value divided by the full width at half maximum height (FWHM).

^bMass accuracy indicates the difference between the measured m/z and the calculated m/z ; mass accuracy is expressed as the relative error = $(\text{Mass}_{\text{measured}} - \text{Mass}_{\text{calculated}}) / \text{Mass}_{\text{calculated}} \times 10^6$ and is given in ppm.

^cMS Scan speed: is given as Dalton per second for QqQ and Q-IT or number of scans per second at a given m/z and a fixed resolving power for Q-TOF, Q-IT Orbitrap, and FT-ICR. Resolution and resolving power change as a function of m/z , and the extent of the change depends on the mass analyzer.

^dUsually QqQ are operated at unit mass resolution.

^eMass accuracy with external calibration.

^fMass accuracy with internal calibration.

^gMS/MS is done in the Q-IT for speed.

biological specimens, particularly with reference to small molecule drugs and metabolites in biological matrices such as blood, plasma, serum, and other biological matrices. The advantage of LC over widely established techniques such as GC is the ability for the separation of compounds that are characterized by low to high molecular weight, having low volatility, are thermolabile and that have a wide range of polarity (from highly polar to hydrophobic).

In the current available literature, the vast majority of forensic papers detailing LC coupled with tandem MS separations involves illicit drugs, therapeutic drugs, metabolites, and poisons. Several reviews have also been written on the subject. There are reports of LC–MS being used to separate amino acids and hypoxanthine in vitreous humor and cerebrospinal fluid with the potential to aid in postmortem interval estimation. Biogenic amines and amino acids in mammalian decomposition fluid have also been analyzed by DI LC-ESI-MS/MS. These compounds showed potential in relating semi-quantitative concentrations and cyclic behavior in target compounds back to the estimation of postmortem interval. To a somewhat lesser extent, LC–MS/MS has also been used for the analysis of gunshot residues, explosives, fiber dye analysis, amino acid analysis from eccrine fingerprint deposits, and chemical and biological warfare agents.

Owing to their chemical instability and polarity, LC is often the technique of choice to separate explosives from other interferences. The analysis of explosives has been typically performed using LC with APCI in the negative ion mode. The identification of compounds such as nitrate esters and 2,4,6-trinitrotoluene (TNT) is of high importance for forensic identification of postblast debris at bombing scenes and also for the detection and monitoring of trace amounts that may be released into the environment. The use of APCI coupled to tandem MS provides a highly specific and sensitive analytical method for the identification of explosive compounds through the formation of an adduct ion in the APCI source. Work by Sanchez et al. developed an LC-APCI-MS method with high levels of reproducibility following a relatively fast analysis time (<30 min) with detection limits in the femtogram-per-liter (fg/L) range. When coupled with tandem MS in forensic cases, the potential for false positives is minimized, making this an attractive analytical method in the forensic field.

Forensic cases involving illicit drugs can present a multitude of issues with regard to analysis, typically as drug seizures often involve large sample numbers with unknown origin and composition. As samples are usually a mixture containing unknown analytes and interferences, analyte extraction and sample cleanup procedures available to the analyst can be varied. Typically, SPE is the most commonly used viable technique. Initially, LC–MS was used where samples were not amenable to analysis by GC–MS because of low volatility (or those that cannot be made volatile by derivatization) or lack of thermal stability. Examples include analysis of LSD (lysergic acid diethylamide), benzodiazepines, tricyclic antidepressants (amitriptyline), and acetaminophen.

High-resolution TOF MS has led some laboratories to implement TOF methods for screening and identification purposes. The ability of TOF to give elemental compositions of compounds allows for the development of exact mass databases. This is particularly useful when new so-called ‘designer drugs’ are developed, as it allows the drug itself as well as

the potential metabolites to be monitored. An example of the application of LC-TOF-MS can be seen in the work by a research group based in Finland, where hair samples were analyzed for 35 different drugs from different classes. The results obtained were in good agreement with the established procedures that utilized analysis of blood and urine by GC–MS.

Currently, LC coupled with isotope ratio mass spectrometry (IRMS) has limited applications in forensic science. Only as recently as 2004, some of the first results were published, detailing the separation of drug molecules using this technique. For example, paracetamol and aspirin, two mass produced and readily available drugs, were separated and identified by monitoring the $\delta^{13}\text{C}$ values with direct loop injection. Although IRMS has the potential to be applied to several forensic samples and cases, the relatively new nature of the technique means that each laboratory has its own experimental design, acceptable standards, calibration methods, and data analysis. IRMS has also been used in a forensic context to analyze explosives, to analyze cotton fibers, and for bullet characterization.

Gas Chromatography–Mass Spectrometry

E Stauffer, Commissariat d'identification judiciaire, Police cantonale Fribourg, Fribourg, Switzerland

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Chromatogram A graphical representation of chromatographic data. It is the record of detector response as a function of time.

Extracted ion chromatogram Graphical representation of the abundance of a single ion versus retention time (RT). Abbreviated EIC.

Extracted ion profile Graphical representation of the abundance of the sum of several ions versus RT. Abbreviated EIP.

Gas chromatography A separation technique in which the mobile phase is a gas. Gas chromatography is always carried out in a column. Abbreviated GC.

Gas chromatography–mass spectrometry A separation technique (gas chromatography) coupled with a detection technique (mass spectrometry). Abbreviated GC–MS.

m/z ratio Mass-to-charge ratio: The mass of an ion divided by its charge.

Mass spectrometry An analytical technique that is used to identify unknown compounds, to quantify known

compounds, and to elucidate the structure and chemical properties of molecules. This is done by converting components of a sample into rapidly moving gaseous ions and separating them on the basis of their mass/charge ratio. Abbreviated MS.

Resolution In chromatography, the measure of the separation of two components. It is a function of the peak width and RT. In mass spectrometry, the measure of the ability of the instrument to distinguish ions of different masses.

Retention time The length of time required for a compound to pass through a chromatographic column and be detected.

Total ion chromatogram Graphical representation of the abundance of a full scan range versus RT. Abbreviated TIC.

Two-dimensional comprehensive gas chromatography A procedure in which all of the separated sample components are subjected to an additional separation step. This is achieved by coupling (using a thermal modulator) two different chromatographic columns. Abbreviated GC×GC.

Abbreviations

EIC	Extracted ion chromatogram
EIP	Extraction ion profile
FID	Flame ionization detector
GC	Gas chromatography or gas chromatograph
GC×GC	Two-dimensional comprehensive gas chromatography

MS	Mass spectrometry or mass spectrometer
m/z	Mass-to-charge ratio
SIM	Selected ion monitoring
TIC	Total ion chromatogram
TOF	Time-of-flight

Introduction

Chromatographic techniques have the power to separate analytes from complex mixtures. However, separating these analytes would not be useful if it was not possible to either detect them or, better yet, to identify them. For this reason, different detectors have been used throughout the years. With simple thin-layer chromatography, or paper chromatography, the naked eye, or an alternate light source, would suffice to detect some analytes. Eventually, a chemical reaction would be triggered. On the more modern gas chromatograph, flame ionization (FID) or photoionization detectors are used, depending on the type of analytes to be detected.

However, the common ground of all these detectors is that they only provide two types of information: the number of analytes and their concentration. Nowadays, particularly in the forensic field, this information does not suffice. One needs to know the identity of a compound or of a series of compounds from a complex mixture.

Mass spectrometry does not simply detect the presence or absence of analytes; it provides structural information about the molecule, often leading to its identification. As such, it is an extremely powerful instrument, but one which quickly becomes impractical when analyzing complex mixtures of analytes. As a matter of fact, its optimal use consists in analyzing pure compounds. This is when the chances of identifying the unknown compounds are greatest.

Thus, the separation power of gas chromatography and the analytical power of mass spectrometry needed to be combined in one full analytical instrument in order to exploit the capabilities of both techniques to their maximum. Chromatography was invented in 1906 by Russian chemist Mikhail Semenovich Tswett and mass spectrometry in 1913 by British physicist Joseph John Thomson. Gas chromatography was invented in 1952 by James and Martin, which allowed the first combined use of gas chromatography and mass spectrometry as a hyphenated technique in 1956 by Roland Gohlke and Fred McLafferty.

The typical setup of a gas chromatograph–mass spectrometer is shown in **Figure 1**. The sample is injected in the gas chromatograph, separated through the column, then goes through the transfer line and is analyzed in the mass spectrometer. A computer controls the overall instrument.

Gas chromatography–mass spectrometry (GC–MS) does not simply add the capability of one to another; it literally multiplies both capabilities and leads to a full analytical instrument. While the specificities of gas chromatography alone (with a simple detector such as FID) and mass spectrometry alone are not great, the combination of both results in an enormous increase in specificity. If two compounds were not to be separated by the chromatographic process, there is a good chance that they would exhibit different structural data and, thus, be distinguished through the mass spectrometer. Similarly, two compounds exhibiting a very close mass spectrum may have a good chance of being separated by the chromatographic process, thus allowing for their distinction. However, one will always find compounds that have very close chromatographic and structural characteristics, for which GC–MS will not be able to make a distinction. This is the case with some structural isomers.

Multiplied Powers

When considering a regular chromatogram, obtained with a simple detector such as FID, the sole information available is the curve constituting the chromatogram. One can extract the retention time (RT) and the peak area, thus the concentration of the analyte if a calibration curve is available. However, it is very possible that another analyte elutes exactly at the same time as the analyte of interest. As such, it is not possible to be sure that the peak in question is the sought-after analyte.

When considering a chromatogram obtained from a GC–MS, the resulting data actually hides another whole layer

of information. For each point on the curve, it is possible to extract a mass spectrum, providing the structural information of the analyte(s) eluting at that time. **Figure 2** illustrates this.

This information consists of a series of mass-to-charge ratio (m/z) peaks with their relative abundance. The most important of these peaks is the molecular ion peak, which corresponds to the unfragmented compound, and the base peak, the most intense peak of the spectrum, normalized to 100%. The other peaks represent the fragments of the molecule, fragments with distribution and relative abundances that are characteristic of the structure of the molecule.

As such, in addition to RT data, one benefits from structural data to identify an analyte. If each analyte in the complex mixture is completely separated from the others, it is then possible to identify with certainty the nature of each analyte. This is where the power of GC–MS comes into play: the capability of identifying almost every component from a complex mixture.

Different Ways of Looking at Data

One great advantage of GC–MS lies in the different ways it is possible to acquire and look at data. Typically, one acquires data using a full scan range, which means that the mass spectrometer is configured to acquire all the m/z within a given range (e.g., 33–400 m/z). The resulting data is called a total ion chromatogram (TIC). It can be seen as a chromatogram identical to one that would be obtained with another simple detector, except that each data entry making the chromatographic pattern contains a full mass spectrum.

The great advantage of the TIC is that all the analytes present in a given sample are detected and recorded. Thus, the chromatogram truly and fully represents the overall content and the analyst has a good panoramic view of what is in the sample. A few disadvantages also exist. The first one is that carrying out a full scan takes time and the resolution of

Figure 1 Typical setup of a gas chromatograph–mass spectrometer. Reproduced from Stauffer E, Dolan JA, and Newman R (2008) *Fire Debris Analysis*, p. 246. Burlington, MA: Elsevier Academic Press. Copyright © 2008, Elsevier.

Figure 2 Total ion chromatogram of a 75% evaporated gasoline sample. Each point on the chromatogram contains a full mass spectrum, as shown with the peaks of 1,2,4-trimethylbenzene, decane and naphthalene.

the chromatogram may not be optimal, thus not allowing for a full separation of some analytes. Second, if one is only interested in the presence of a given or a set of given analytes, these may not stand out within the overall pattern of the mixture. Third, the sensitivity of the full scan range is not as good as the one that would result from the scan of just a few ions. The more m/z are scanned, the worse the sensitivity. Thus, some trace analytes may simply not be detected or distinguished from the background signal.

As an alternative, it is possible to use a selected ion monitoring (SIM) rather than a full scan. In this situation, the user decides which ions must be monitored. The MS will then scan only for these m/z and ignore all of the others. This allows for a quasi-complete suppression of the matrix interferences: only the analytes sought after are detected. It also significantly improves the sensitivity since each scan covers only a couple of dozens m/z rather than a full range of 300 or more m/z , for example. One major disadvantage in this configuration is that the analyst completely loses the overall view of the sample. Because only a partial image of what is in the sample is obtained, it is not possible to take into account the overall composition of the sample during the interpretation of the results. If the full scan corresponds to a wide-angle view, SIM would correspond to a super telephoto view.

Some analyses are better carried out using SIM and some others using a full scan. Analyzing a sample of unknowns would naturally require a full scan, since one does not know in advance which analytes are sought after. Conversely, performing routine analysis for some specific known metabolites in trace amounts, for which their presence and quantity are not influenced by the content of the matrix, is best performed using a SIM configuration. In fire debris analysis, for example, even though the analytes sought after are quite known, it is not recommended to carry out only SIM. As a

matter of fact, it is important to have a good view of the content given off by the sample's matrix, since it is taken into consideration in the interpretation of the results. However, it is recommended in some instances, after performing a full scan range, to carry out a second analysis, under a SIM mode, to improve the sensitivity of the GC–MS and to provide further data.

When using a full scan, it is still possible to benefit from the mass spectral data. Starting from the TIC, one can selectively display some individual m/z , leading to an extracted ion chromatogram (EIC), as shown in [Figure 3](#), or a sum of several m/z , leading to an extracted ion profile (EIP), as shown in [Figure 4](#). When comparing [Figures 3](#) and [4](#) to [Figure 2](#), one quickly realizes the advantage of extracted ions in interpreting chromatograms and identifying classes of compounds.

This provides the advantage of first having a complete view of the sample through the full scan and second, looking at specific compound-related patterns through the EIC or EIP. This allows the data to be filtered through the partial removal of matrix interferences or other analytes and for the pertinent data to be revealed. The great advantage of EIC and EIP is that it does not filter at the data acquisition, thus the full data always remains available.

Requirements

In order to combine a gas chromatograph to a mass spectrometer, a few conditions must be met.

First of all, the sample must be suitable for injection into the mass spectrometer. This is naturally achieved because the mobile gas phase exiting the GC with the analytes is perfectly suitable for entry into the MS, where it will first be ionized and then filtered, to be finally detected.

Figure 3 Example of extracted ion profiles from a 75% evaporated gasoline sample. One can clearly see the patterns exhibited by the different classes of compounds. Reproduced from Stauffer E, Dolan JA, and Newman R (2008) *Fire Debris Analysis*, p. 316. Burlington, MA: Elsevier Academic Press. Copyright © 2008, Elsevier.

Second, it is important to realize that in order to obtain a mass spectrum, a certain amount of time is required. This time depends on the type of detector and the scan range (typically something like 30–400 m/z). The larger the scan range, the longer the scan takes. In order to obtain full separation of

coeluting compounds, the resolution of the chromatogram must be high enough to allow for the separation of the peaks. Thus, if two compounds elute within 4 s and the MS makes one full scan every 4 s, the compounds will not be separated and the specificity of the instrument will strongly suffer.

Figure 4 Example of extracted ion chromatograms from a 75% evaporated gasoline sample. One can clearly see the patterns exhibited by the different ions representative of organic compounds. Reproduced from Stauffer E, Dolan JA, and Newman R (2008) *Fire Debris Analysis*, p. 317. Burlington, MA: Elsevier Academic Press. Copyright © 2008, Elsevier.

In practice, all modern MS exhibit a scan rate high enough (2–10 Hz) to allow for a good chromatographic resolution. However, the chromatographic resolution obtained with a regular GC–MS is definitely lower than that obtained from a GC–FID for example. The reason is that the FID has a scan rate of approximately 200 Hz. Actual MS scan rates are not considered an issue for regular GC–MS; however, they become a concern with new methods such as two-dimensional comprehensive gas chromatography–mass spectrometry (GC×GC–MS). In this case, all the components coming out of the first gas chromatograph are subjected to a second separation (based on different characteristics) in another chromatograph. The scan rate must be of at least 50 Hz, thus allowing for enough MS scans during the time required for the second separation. This scan

rate can only be achieved with a different MS technology: time-of-flight mass spectrometry (TOF–MS).

Instrumentation

There are very few variations regarding the gas chromatograph. All modern chromatographs use a capillary column with a coated stationary phase, which offers a very high resolution. The injection techniques, split or splitless, are also available on all gas instruments.

The main variation found in a GC–MS lies in the MS, which offers different major alternatives. There are three types of mass spectrometers available on the market today:

Figure 5 An Agilent 6890N-5975 gas chromatograph-mass spectrometer. An Agilent 7683B autosampler is present above the GC on the left. Reproduced from Stauffer E, Dolan JA, and Newman R (2008) *Fire Debris Analysis*, p. 246. Burlington, MA: Elsevier Academic Press. Copyright © 2008, Elsevier.

quadrupole, ion trap, and TOF. Each presents its advantages and drawbacks and some are more suitable for some types of analysis than others. **Figure 5** shows a typical GC-MS setup in a forensic laboratory.

With the computer controlling system and the autosampler, a modern GC-MS is a highly capable instrument that can guarantee a very high throughput. This provides tremendous relief in terms of the manpower requirement for a forensic laboratory. The convenience of its use is also an important factor contributing to its reputation as a gold standard. Basically, it is possible to fully automate the separation of 150 complex mixtures, including the identification of their analytes. In other words, one can let the instrument run by itself for several days without worrying about it and just concentrate on the interpretation of the results.

Forensic Applications

The applications of GC-MS to the forensic field are extremely diverse. Basically, all analytes that can go through a gas chromatograph can be analyzed by GC-MS. So, everything that is volatile under 300–500 °C, does not decompose at these temperatures, and exhibits a molecular weight below 600 amu (up to 1000 with new MS) can be analyzed by GC-MS. This leaves room for many different applications, which is the reason why GC-MS is one of the most versatile analytical instruments that one can find in a forensic laboratory.

The most common applications in forensic science are the analysis of fire debris, drugs, explosives, and toxins. Other applications, less often encountered, include the analysis of hydrocarbons in environmental crime investigations, vegetable oil residues, and, when using pyrolysis-GC-MS, paints, fibers, and plastics.

In fire debris analysis, ignitable liquid residues extracted from fire debris samples are analyzed in order to detect for the presence of an ignitable liquid, possibly used as an accelerant at a fire scene. These samples consist of complex mixtures of hydrocarbons, often unresolved. The power of MS is fully

exploited by using EIC and EIP to interpret the complex chromatograms. Because of the type of organic molecules, it is possible to extract different profiles using several specific ions and, thus, to facilitate the interpretation of the chromatograms. Fire debris analysis is mostly concerned with qualitative, maybe semi-quantitative, analysis.

In drug analysis, the forensic scientist is presented with unknown samples of powder or liquid and must determine the nature and quantity of its components. Not all drugs can be analyzed through GC-MS, given that some are sensitive to the heat of the injector, for example. However, the analysis can be carried out on most drugs. With many drugs, such as cocaine and heroin seized from the street, GC-MS provides a very thorough analysis. Determining that an active substance is present and at what quantity is an important element for the prosecution. However, identifying the adulterants and the contaminations/impurities also present brings a whole new edge to the investigation. As a matter of fact, adulterants and contaminations/impurities are used to perform drug profiling, a method capable of establishing links between individual seizures and identifying the drug network. GC-MS is a primordial tool in this regard, since it allows for a complete separation and identification of unknowns in a substance. Because MS is not always optimal in quantitative analysis, it is often used in conjunction with other detectors, such as FID, to obtain both qualitative and quantitative accurate results.

In explosive analysis, the goal is to analyze seized substances or residues of possible explosives. Again, the scientist not necessarily being aware of the type of substance involved, GC-MS's versatility brings a great advantage to the identification of explosives and residues. It is considered as a sufficient technique to allow for the identification of many explosives without any other testing.

Forensic toxicology is a wide field concerned with the detection of drugs, metabolites, or toxins in the human body. This ranges from simple medication to alcohol consumption and other drug-related substances. The samples are body fluids such as blood and urine and other body samples, such as hair, tissues, or fingernails. The separation and identification power of GC-MS presents an interesting advantage, even though not all substances can be run through GC-MS. A forensic toxicology lab includes many other analytical instruments such as liquid chromatography, capillary electrophoresis, and immunoassay. As such, GC-MS is one important tool among others, such as liquid chromatography-mass spectrometry (LC-MS), in a forensic toxicology laboratory.

In environmental crime investigation, one is often confronted with hydrocarbon spills or contaminations. Because hydrocarbons are extremely complex mixtures of hundreds of components, the separation power exhibited by GC and the characterization power of MS are fully necessary. As a matter of fact, environmental laboratories often use specific parameters, in terms of separation, that are quite different from parameters used in traditional forensic settings, because of the complexity of the substances they are dealing with. The ultimate goal of an environmental investigation is not to simply demonstrate that the pollution exists, as one rarely needs a GC-MS for that; however, it is to identify the source of the pollution. In this scope, different techniques of oil spill fingerprinting, for example, have been developed over the years.

The analysis of vegetable oils (or rather their derivatives) by GC–MS has been well known for many years in the food industry. In fire investigation, a method has been developed to recover vegetable oil residues from a fire that could have been triggered by the autoignition of oil residues. This method uses GC–MS to analyze the extract and to identify the type of oil involved. GC–MS is clearly the best instrument to carry out this type of analysis, because of its combined separation and analytical power.

Finally, many other samples can be analyzed by GC–MS. This is the case with plastics, polymers, paints, and fibers whose composition can be analyzed after being pyrolyzed. This provides important information regarding a common source between a questioned and a comparison samples. In this regard, pyrolysis-GC–MS was developed, allowing for the direct injection of pyrolysis products into the GC. This technique, less often encountered, has also been used for many years in different crime laboratories around the world.

Glossary

Base peak Most abundant ion in the mass spectrum.

In plotting the mass spectrum, all other ions are normalized to the base peak.

Effluent In chromatography, the mobile phase containing separated compounds eluting from the chromatographic column.

Mass spectrum Graph of ion intensity versus m/z for a particular molecule, relative to the most abundant ion.

Mass-to-charge ratio The mass of an ion divided by its charge, often given as m/z .

Molecular ion The ionized form of the sample molecule, typically formed through addition or loss of an electron or proton.

Resolution The ability of the mass analyzer to display two separate peaks for ions of similar masses.

Transmission The ratio of the number of ions passing through the mass analyzer and reaching the detector to the number of ions produced in the ion source.

Introduction

Mass spectrometry (MS) is a widely used instrumental technique, with the first such instrument, known as a parabola spectrograph, being reported in 1912. Since then, numerous advances and improvements in MS have made this technique a mainstay, first in physics laboratories and now in analytical chemistry and forensic science laboratories.

MS is based on ionization and fragmentation of sample molecules in the gas phase. Since molecules fragment in a unique manner, the resulting ion fragmentation pattern can be used to obtain structural information for a given molecule. In forensic science, MS has become the technique of choice for the definitive identification of a wide variety of evidence including controlled substances and fire debris. In these cases, the mass spectrometer is normally coupled with either a gas chromatography (GC) or liquid chromatography (LC) system and is used as the detector; that is, separation of the sample is achieved via chromatography and the separated compounds enter the mass spectrometer sequentially for ionization, separation, and detection of the generated ions. Coupling the chromatography system to the mass spectrometer in this way yields two pieces of information for each analysis: retention time and mass spectral information for each separated compound, both of which can be used for comparison with suitable reference standards.

Instrumentation

A mass spectrometer consists of five major components: a vacuum system, an ion source, a mass analyzer, an ion detector, and a data recording system, as shown in Figure 1. In general, ions of the sample are produced in the ion source and then accelerated to the mass analyzer where they are separated according to their mass-to-charge (m/z) ratio. The separated ions reach the detector where the intensity of each m/z is recorded. The ion signal is then amplified and digitized in the data recording system, generating the mass spectrum,

which is a plot of intensity versus m/z , normalized to the most abundant ion.

The mass analyzer, ion detector, and other components of a mass spectrometer are maintained in the vacuum system, which can reach pressures as low as 10^{-9} torr ($\sim 1.33 \times 10^{-7}$ Pa). Operating under vacuum increases the mean free path of the gas-phase ions generated, which is necessary to prevent unwanted collisions with neutral molecules in the system. Such collisions could result in a loss in sensitivity or an increase in the complexity of the resulting mass spectrum, making subsequent spectral interpretation more difficult.

Sample Introduction

Numerous methods have been developed to introduce samples into the mass spectrometer, varying according to the type of sample. Relatively pure solid samples can be introduced into the ion source using a direct insertion probe via a vacuum interlock system. Alternatively, liquid or gaseous samples can be continually sampled into the ion source using a membrane interface. More recently, atmospheric pressure interfaces have been developed in which the sample is ionized at atmospheric pressure and the resulting ions are transferred to the mass analyzer through a series of focusing lenses and differentially pumped regions.

In gas chromatography–mass spectrometry (GC–MS) and liquid chromatography–mass spectrometry (LC–MS) systems, the sample is first injected into the chromatography system where separation into individual compounds occurs. The separated sample compounds are then transferred into the mass spectrometer where ionization occurs in the ion source. The resulting ions and fragments are then transferred to the mass analyzer for separation according to m/z , and the separated ions are then detected in the ion detector.

While chromatography and MS are now commonplace in modern forensic science, the development of such hyphenated techniques was initially hindered by the difference in operating pressures: chromatography occurs at atmospheric pressure while MS operates under vacuum. In modern

Figure 1 Schematic representation of a mass spectrometer.

GC–MS systems, the common use of capillary columns (internal diameter ~ 0.10 – 0.53 mm) means that nominal mobile-phase flow rates around 1 ml min^{-1} are typically used. Since these flow rates are compatible with the vacuum system, the chromatography column can be fed through a transfer line from the GC oven into the ion source of the mass spectrometer. The transfer line is heated (~ 250 – 300°C) to prevent loss of separated compounds through condensation. On eluting from the column into the ion source, the lighter mobile-phase gas diverges and is pumped away by the vacuum system while the sample compounds are ionized in the source.

In modern LC–MS systems, atmospheric pressure ionization interfaces are used to overcome the issue of the higher flow rates (~ 0.1 – 10 ml min^{-1}) common to LC. That is, the effluent from the LC column is ionized at atmospheric pressure and the ions are sampled through a series of apertures into the mass analyzer for subsequent separation and detection.

Ion Source

In the ion source, sample molecules are ionized by one of many available techniques. Under vacuum conditions, electron and chemical ionization are common, particularly in commercially available GC–MS instruments. In terms of atmospheric ionization, electrospray and atmospheric pressure chemical ionization are popular choices, especially in commercial LC–MS instruments.

Electron Ionization

Electron ionization occurs through interaction of the gas-phase sample molecules with high-energy electrons emitted from a resistively heated filament. After emission from the filament, the electrons are focused through a narrow slit and attracted to an anode that is positioned ~ 15 – 20 mm opposite the filament. The ion source may also contain a magnet and, under the influence of the magnetic field, the emitted electrons travel

in spiral pathways toward the anode, increasing the probability of interaction with sample molecules.

The ionizing electrons approach the electron density cloud of the sample molecule, transferring kinetic energy. Since the energy of the electrons is typically 70 eV , sufficient energy is transferred to efficiently overcome the first ionization potential of most organic compounds (i.e., the removal of an electron) to form a positively charged sample ion. This first formed ion is termed the molecular ion and has a mass nominally equivalent to the molecular mass of the sample molecule. Following ionization, the excess energy transferred causes fragmentation of the molecular ion, yielding a series of fragment ions that are unique to that molecule under those ionization conditions. The ion source also contains an extractor plate and an ion focusing plate that are maintained at a negative potential, thus attracting the positively charged ions and accelerating them toward the mass analyzer.

Electron ionization causes extensive fragmentation of the molecular ion, yielding rich structural information for the sample molecule. However, depending on the extent of fragmentation, little to no molecular ion may be detected (i.e., the molecule is mostly or fully fragmented), potentially making a definitive identification more difficult.

Chemical Ionization

Chemical ionization uses a reagent gas to ionize sample molecules through ion–molecule reactions in the gas phase. The reagent gas (e.g., methane) first undergoes electron ionization, generating a molecular ion which then fragments and/or reacts with other reagent gas molecules and ions. Since the reagent gas is present in significantly higher concentrations than the sample, ionization of sample molecules occurs through reactions with reagent gas ions, rather than by electron ionization. Depending on the nature of the sample molecule, ionization reactions include proton transfer, proton abstraction, and adduct formation, resulting in pseudo-molecular ions of the sample, while regenerating the reagent gas. Molecular mass information can be discerned from the resulting sample ions

but, since these ions do not have significant excess energy, as would be the case in electron ionization, little fragmentation occurs. Hence, chemical ionization is a 'soft' ionization process, yielding molecular mass information but little structural information. As a result, chemical ionization is complementary to electron ionization and is particularly useful in the analysis of molecules that fragment excessively under electron ionization conditions.

Electrospray Ionization

Electrospray ionization (ESI) is an atmospheric pressure ionization process commonly used in commercial LC-MS systems. The electrospray source consists of a capillary tube, through which the effluent is pumped, and a counter-electrode. A potential difference applied between the tip of the capillary and the electrode creates an electric field, which results in an accumulation of charge at the surface of the liquid as it emerges from the end of the capillary. A nebulizing gas can be introduced to mechanically assist droplet formation while a drying gas can also be used to aid solvent evaporation from the droplets. As the solvent evaporates, the droplet size decreases, while the electric charge density on its surface increases. Repulsion between like charges eventually overcomes the surface tension forces of the droplet, breaking up the droplet to produce smaller droplets. The process repeats, producing smaller and smaller droplets and eventually results in the ejection of an ion from the droplet. These gas-phase ions pass through a sampling cone and are focused into differentially pumped vacuum regions before being transported into the analyzer of the mass spectrometer. As with chemical ionization, ESI is also considered a 'soft' ionization method although in contrast to chemical ionization, this procedure commonly produces multiply charged ions. As a result, ESI is ideal for the analysis of large, nonvolatile molecules, which may be difficult to analyze otherwise.

Atmospheric Pressure Chemical Ionization

Atmospheric pressure chemical ionization is also used as an interface in LC-MS systems, with an interface similar to that described for ESI. In this case, the column effluent is pumped through a pneumatic nebulizer, often in the presence of a nebulizing gas such as nitrogen, to create a fine spray. The resulting droplets pass through a heated chamber where desolvation and vaporization occur. Ionization then occurs at a corona discharge electrode, in a similar manner to that described previously for chemical ionization. That is, ions of the nebulizing gas are formed via electron ionization processes at the corona discharge. These ions collide with solvent (i.e., mobile phase) molecules, forming secondary reagent gas ions which subsequently transfer charge to sample species. The collisions occur with high frequency, resulting in very efficient ionization of the sample, typically yielding molecular ions with little fragmentation.

Mass Analyzer

From the ion source, the fragment ions are accelerated and focused into the mass analyzer where they are separated

according to m/z . As with ion sources, numerous different mass analyzer designs have been developed, varying in the means by which ions are separated, as well as in the transmission, upper mass range, and resolution of the analyzer. Transmission is expressed as the ratio of the number of ions that pass through the analyzer and reach the detector to the number ions produced in the ion source. The upper mass limit is the highest m/z that can be measured while the resolution is a measure of the analyzer's ability to record two distinct peaks for ions with very similar masses.

Sector Mass Analyzer

During mass analysis in a sector mass analyzer, ions are separated under the influence of an applied magnetic or electric field. In the magnetic sector analyzer, ions from the source are under the influence of an applied magnetic field while traveling toward the detector. The magnetic field causes ions to travel with curved trajectories, with the radius of curvature dependent on the acceleration voltage and magnetic field strength. For a given voltage and field strength, only ions with a specific m/z will follow the correct radius of curvature to reach the detector. Thus, by scanning either the voltage or field strength, ions of different m/z reach the detector. An electrostatic analyzer can also be incorporated before the magnetic sector (double-focusing) to enhance the focus of ions with the same m/z but slightly different kinetic energies, resulting in improved resolution.

Time-of-Flight Mass Analyzer

The time-of-flight analyzer is notable in that separation of ions occurs in a field-free region. Ions from the source are accelerated to the same kinetic energy and the time taken for these ions to drift through the flight tube is measured. Despite having the same kinetic energy, ion velocities differ due to differences in m/z . Smaller, lower-mass ions have greater velocity and, hence, travel faster through the flight tube. These ions reach the detector before higher-mass ions, resulting in separation.

Neither sector nor time-of-flight mass analyzers are routinely used in forensic science. However, the latter analyzer has recently been coupled to a relatively new ionization technique, known as direct analysis in real time (DART). This technique allows ionization of samples under atmospheric pressure, with little to no sample preparation. This combination of DART with the time-of-flight mass analyzer has become more common in forensic applications, particularly in the analysis of controlled substances. Nonetheless, the time-of-flight mass analyzer is not yet routinely used in forensic laboratories. The commercially available GC-MS and LC-MS systems that are more commonly used typically contain quadrupole or ion trap mass analyzers, as described below.

Quadrupole Mass Analyzer

The quadrupole mass analyzer consists of four parallel conducting rods of hyperbolic cross section spaced about a central axis along which ions are conducted. The rods are connected to radiofrequency (RF) and direct current (DC) generators, and

adjacent rods are of opposite RF phase. For a given set of RF and DC potentials, only ions within a narrow m/z range will have a stable trajectory and reach the detector; all other ions will hit the rods and be neutralized. In full mass scan mode, the RF amplitude and DC voltage are scanned, while maintaining a constant ratio, such that ions with increasing m/z reach the detector. However, a drawback to full mass scan mode is that ions of each m/z only spend a very short time in the analyzer and, hence, only a small fraction actually reach the detector per scan cycle. To improve sensitivity, selected ion monitoring can be used, in which the RF and DC voltages for specific ions of interest are applied. Since fewer m/z are scanned during a given scan cycle, a greater proportion of ions of the targeted m/z reach the detector, leading to increased sensitivity.

Ion Trap Mass Analyzer

The ion trap mass analyzer consists of a ring electrode with end-cap electrodes positioned above and below. Typically, ions are formed outside the trap and then transported into the trap through a small aperture in one of the end-cap electrodes. Ions of all m/z are stored in the trap, undergoing harmonic oscillations in three dimensions, with ions of each m/z oscillating at a characteristic frequency. A damping gas such as helium is often introduced to the trap to facilitate efficient capture of ions during injection and also to permit collision-induced dissociation.

In commercial instruments, an RF voltage with constant frequency but varying amplitude is applied to the ring electrode. By scanning from low to high RF amplitudes, ions with progressively higher m/z become unstable and are ejected from the trap to obtain a full mass scan.

Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) involves two separate stages of mass analysis and can be used to decipher relationships among ions in a mass spectrum or to identify compounds in complex mixtures that have not been subjected to prior separation. While many types of MS/MS scans are available, the most commonly used is the 'product ion scan' which involves isolating the ion of interest (all other ions are removed), fragmenting the ion, and then collecting a mass spectrum. This results in a spectrum containing only ions originating from the ion of interest.

MS/MS experiments can be conducted in two ways, referred to as 'tandem-in-space' or 'tandem-in-time.' The former requires at least two distinct mass analyzers, although triple quadrupole instruments are commonly used. These instruments consist of three quadrupoles in series: the first and third are used as mass analyzers while the second is an RF-only quadrupole that acts as a collision cell. For a product ion scan, the ion of interest is selected in the first quadrupole and accelerated into the second quadrupole, undergoing collisions with a reagent gas. The fragment ions resulting from these collisions are scanned in the third quadrupole, generating the mass spectrum.

Alternatively, an ion trap mass analyzer can be used for 'tandem-in-time' MS. In this case, selection of the ion of

interest, fragmentation, and collection of the resulting ions are all conducted within a single trap. Initially, the desired m/z is stored in the trap while all others are ejected by applying a broadband waveform that accelerates ions of all m/z except the ions of interest. The remaining ions are then accelerated to nonejecting velocities such that they collide with the helium damping gas and undergo fragmentation. By then scanning the RF amplitude, the fragment ions are sequentially ejected from the trap to the detector and a spectrum is generated that contains only ions originating from the ion of interest.

Ion Detector

The most common type of ion detector used in GC-MS and LC-MS instruments is the electron multiplier, due to its compact nature, signal amplification ability, and relatively low cost. The multiplier is horn-shaped and composed of glass, coated with a semiconductive substance, such as lead oxide, that readily emits secondary electrons when impacted by energetic particles. The outermost end of the multiplier is held at a high potential while the innermost end is referenced to ground. Ions from the mass analyzer can be accelerated to the outer end of the multiplier where, upon collision with the multiplier surface, several electrons are emitted. These electrons are attracted further into the multiplier, undergoing additional collisions with the surface. Each time an electron collides with the surface, additional electrons are emitted. As a result, the ion beam leaving the mass analyzer is converted into a cascade of electrons. Most multipliers yield signal amplification on the order of 10^5 – 10^6 . The resulting current is digitized in an analog-to-digital converter and sent to a computer system where the mass spectrum is generated.

Data Interpretation

The mass spectrum is a graphical plot displaying relative abundance on the y -axis and m/z on the x -axis. The highest mass ion present is typically a form of the molecular ion, with the particular m/z depending on the ionization technique used. The most abundant ion in the spectrum is known as the 'base peak' and is assigned an abundance of 100%. The abundance of all other fragment ions is then expressed relative to the base peak.

The complexity in data interpretation, as well as the information attainable, depends in large part on the ionization technique employed. Electron ionization can yield dozens of singly charged fragment ions, providing rich structural information. Conversely, a technique such as ESI may provide multiply charged ions, which is useful for analyses on instruments with limited m/z ranges. Whatever the ionization technique, oftentimes a molecule will fragment in a unique and reproducible manner and, thus, the mass spectrum is characteristic of that molecule and comparable to spectra collected elsewhere under similar conditions.

As an example, a simplified spectrum of the normal alkane, decane ($C_{10}H_{22}$), obtained under electron ionization conditions is shown in [Figure 2](#).

Figure 2 Schematic representation of the mass spectrum for decane ($C_{10}H_{22}$).

The molecular ion is present at m/z 142 since the molecular mass of decane is 142 u. A series of ions at m/z 85, 71, 57, and 43 are also present, representing fragmentation of the molecular ion. Note that there is a difference of 14 u between these successive fragment ions, which corresponds to losses of CH_2 groups from the molecule. Like the normal alkanes, other chemical classes have their own distinct spectral features that can be used for identification purposes in a similar manner.

Coupling a mass spectrometer with an ion source such as an inductively coupled plasma (ICP) generates elemental information for each sample analyzed. The ICP source consists of a very hot body of gas, typically argon, which acts to atomize and ionize the sample. The resulting ions are transported into the mass spectrometer for subsequent separation and detection. From the mass spectrum generated, the elemental composition of the sample can be determined based on the masses of the ions present. Nearly all elements in the periodic table can be detected using ICP-MS, with detection limits ranging from the low parts per billion ($\mu g\ l^{-1}$) to the subparts per trillion ($ng\ l^{-1}$) range.

Forensic Applications of MS

In forensic analyses, an unknown sample can be identified based on comparison of its mass spectrum with a library database of mass spectra. Search algorithms are used to compare the spectrum of the unknown to those in the database, typically reporting at least the top ten 'matches.' However, even for a true match, there may be subtle differences between the mass spectrum of the unknown and the mass spectrum in the library. These differences can occur due to slight differences in the instrumentation and ionization conditions under which the library spectra were obtained compared to the conditions under which the spectrum of the unknown was obtained.

Such problems can be overcome by analyzing a suitable reference standard on the same instrument and under the same conditions as the unknown sample. The resulting two mass spectra are then compared to determine whether the spectrum of the unknown and that of the reference standard 'match.' However, the criteria to determine a 'match' vary across forensic laboratories. Typically, the molecular ions should be at the

same m/z in each spectrum being compared and the base peaks should be present at the same m/z in the two spectra being compared. The ratios of the six or eight most abundant ions should also be similar between the two spectra.

Although LC-MS is gaining popularity and becoming more common in forensic laboratories, GC-MS is more widely utilized for identification purposes in many of the forensic science disciplines. For controlled substances, the retention time and mass spectra are compared between a submitted sample and reference standard to identify any illicit drugs present. In fire debris analysis, an extract of the debris is analyzed by GC-MS and the resulting chromatogram and mass spectra are compared to a database of known flammable liquids. Definitive identification of a flammable liquid in the debris is indicative of an intentional, rather than accidental, fire. Explosive residues or suspected explosive materials can be extracted and analyzed by both GC-MS and LC-MS to definitively identify the explosive, or components of the explosive, used. Furthermore, pyrolysis GC-MS can be used for the analysis of solid samples. In this technique, the sample is pyrolyzed prior to analysis, and the resulting breakdown products are sufficiently volatile for GC analysis. Samples such as fibers or paint fragments can be analyzed by pyrolysis GC-MS and, since the mass spectrometer is used as the detector, these samples can be characterized and identified for comparison with reference standards and/or spectral databases.

In recent years, there have been a number of advances in MS that have shown potential for forensic applications. DART, coupled with a time-of-flight mass analyzer, has already been introduced in a number of laboratories across the country, with a particular emphasis on controlled substance analysis. Although matrix-assisted laser desorption/ionization (MALDI) is not a new ionization technique, forensic applications of MALDI coupled with time-of-flight MS have only relatively recently become more commonplace. Example applications include the analysis and identification of pigments and dyes, condom lubricants, and adhesives, as well as numerous DNA applications. Since the field of forensic science is constantly evolving, it is conceivable that these advances will be incorporated into routine analysis of a variety of different evidence types in laboratories throughout the country.

Glossary

Brightfield microscopy Viewing a sample with light that is transmitted through it, typically on a compound microscope.

Compound microscope A microscope that uses a combination of lenses to increase final magnification and improve image resolution.

Fluorescence The luminescence of a sample that persists as long as the sample is excited by radiation (light) of a high-enough wavelength.

Phase contrast microscopy Viewing a sample on a compound microscope that has been fitted with special optics (silvered rings and disks) to translate phase difference into amplitude, providing analytical information.

Polarizing light microscopy Viewing a sample on a compound microscope that has been fitted with special filters that orient the light rays providing analytical information about the sample.

Stereomicroscope A microscope that provides a stereoscopic view of a sample.

Introduction

In electron microscopy, 'analytical microscopy' means the addition of any compositional or material analysis instrumentation to an existing microscope; the combination of instrumentation expands its capabilities from observation to separation and identification of constituent components, be it elemental (with energy or wavelength dispersive spectrometry), atomic (as with backscattered electron images), or structural (crystallography). No such clear divisions exist in light microscopy, however, and the phrase 'analytical light microscopy' actually covers a range of disparate methods that center on one common aspect: the microscope.

Light microscopy has many and varied applications in the forensic sciences and provides the canonical example of 'detection': The seeing of things that are beyond the unaided eye. The smallest items of evidence, or even the remnants of that evidence, can be detected, resolved, and imaged. Typically, minimal sample preparation is required and the process of microscopic analysis is non-destructive. The varied applications range from firearms to documents, serology, and the obvious trace examiner comparing hairs, fibers, paints, or soils. Although each scientist may use different microscopes and methods in various ways, he or she is relying on the magnification and resolving power of the microscope.

Magnification and resolution are the two main purposes of a microscope, to create an enlarged image of an object that is clear and distinct. These two purposes, however, conflict with each other and as magnification increases, resolution can decrease unless steps are taken to adjust the system to improve the viewing of fine details. Resolution, the ability to distinguish between two objects at a magnification, is often overlooked in favor of the notion of simply increasing magnification: Greater resolution means greater detail while greater magnification means merely a larger image.

Forensic microscopy covers many types of samples, from opaque solids to nearly transparent fluids, and from large scale surfaces to the tiniest particulates. Many types of samples require little to no preparation for viewing; others require substantial treatment depending on the types of minute

features that are to be examined. Specimen types that do require treatment also exist within a range of methods, from simple reconstitution of a dried sample with water to sectioning, staining, and mounting. At a minimum, some type of mounting medium is required to adjust for the refractive index of the sample and the air to improve viewing.

Microscopes Used in Analysis in the Forensic Sciences

Stereomicroscope

Stereomicroscopes are the simplest type of microscope and are, therefore, used less in analytical microscopy in its truest sense than other types of microscopes. In fact, it is less the microscope than the lighting that provides the 'analysis' with a stereomicroscope. Various wavelengths of light can provide luminescence or fluorescence in a sample, which can then be viewed with a stereomicroscope. At the levels of magnification found in a stereomicroscope (typically between 2.5X and about 100X), the 'analysis' is actually detection or presumptive testing. Using a stereomicroscope on a boom-arm allows the microscope to be used over large objects, such as automobiles or clothing. Photography and videography are relatively easy with stereomicroscopes. Small and inexpensive digital instruments are now available for use in the field and the laboratory.

Compound Microscope

The workhorse of microscopy, the compound microscope provides both greater magnification (2.5X to slightly over 1000X) and, given the right lensing systems, increased resolution. The compound microscope can use either reflected light, as with bullets or tool marks, or transmitted light, as with trace materials, to image specimens. The microscopes are manufactured for use as one or the other and are rarely switched. In transmitted light, specimens must be thin enough for the light to pass through it and reveal features. Unless the sample is already semi-transparent or translucent, some sample preparation will be required. Care is required as sample preparation can produce

unwanted features (artifacts) that can obscure or even mislead the unwary microscopist.

This last point leads to the importance of morphology in microscopy. Although the idea of an object's shape may not seem 'analytical', it is a key discriminant in deciding whether something belongs to a particular class or not; in this sense, it is the first step (and, given significant differences, maybe the last) in analysis. As Gallagher and Thornton note,

Microchemical testing will deliver composition. If a sample has a discernible structure, however, the trace analyst should not rush to microchemical testing. Knowledge obtained about composition should not be subordinated to knowledge of structure. For example, instrumental analysis might indicate that an evidence compound is silicon dioxide, SiO_2 . While the analysis may be entirely valid and the composition is useful information, this alone will not tell us whether the sample is quartz, vitreous silica, agate, amethyst, carnelian, chalcedony, flint, jasper, onyx, prase, rose quartz, or Tiger's Eye. Optical properties of the type that can be determined by microscopy will distinguish between these various forms, however.

The successful microscopist will learn to analyze morphology as keenly as he or she learns the other methods discussed herein.

Microchemical analysis is also a core technique in forensic science, whether using manual or instrumental methods. Conservative of sample and specific to material, many 'wet chemical' methods can be carried out on the smallest of samples; see particularly Chamot and Mason's and McCrone's work in this area.

Compound microscopes can be configured to operate in brightfield (standard), comparison, polarized light, phase contrast, hot stage, and fluorescence.

Brightfield

Brightfield microscopy is used when examining a specimen's morphology and internal features. The kinds of samples that can be examined using brightfield microscopy are innumerable; as long as they can be prepared for transmitted light viewing, they are amenable to brightfield examination. The appropriate preparation for a particular sample depends on the sample, its form, and the information that is to be gleaned from it. Choice of a mounting media is critical to providing the desired contrast and to avoid extraneous signals, such as fluorescence.

Comparison

A comparison microscope is composed of two compound microscopes optically joined to provide a real-time split view. The sample on the right-hand stage appears on the right side and the left-hand sample on the left, in the field of view. This simultaneous viewing is critical for comparing two samples: Too much information is being consumed by the brain to hold it and then mentally compare it to a new sample. Light levels and optical settings must be matched between the two microscopes; otherwise, the two samples will not appear the same. Most modern comparison microscopes now have one light source and two fiber optic leads that keep the light even between the two microscopes. Photography is particularly important in comparisons, as it affords the closest appreciation others can have for what the

microscopist saw at the time of examination. Types of analysis detailed later in this chapter can be added to a comparison microscope, strengthening the analytical capabilities of the instrument even more. Multiple comparisons under multiple conditions with no significant differences, increases the likelihood of common sourcing.

Polarized light

Learning to use a polarized light microscope, or PLM, opens up a world of analytical possibilities for the forensic scientist. Polarized light microscopy yields qualitative information and quantitative data that can be extremely discriminating. On a standard brightfield microscope, two polarizing filters are introduced into the light path, one between the sample and the light source (called the polarizer) and one between the sample and the oculars (the analyzer). The polarizer restricts the light coming from the source into the sample to one preferred pathway; any light that passes through the sample is now influenced by the sample's internal structure. The stage on a PLM rotates, allowing the sample to rotate around the axis of the polarizer, providing gradations of response to the polarized light. Specimens can be viewed solely in plane polarized light, to determine traits such as refractive index, sign of elongation, and pleochroism, or between crossed polars (where the analyzer is introduced to the light path) to determine birefringence and to view interference colors resulting from the interaction of the light passing through the sample being resolved on the analyzer. Filters and compensators can also be introduced into the light path to adjust images for contrast or to determine optical properties.

Hot stage

Compound microscopes can be fitted with thermally-controlled stages (so-called 'hot stages') that can heat samples up to 350 °C. Although inherently destructive, the hot stage method can help identify materials, particularly thermoplastic polymers, or compare materials' response to various temperatures. Although hot stage microscopy has been largely supplanted by other types of analysis, mainly spectroscopy, it can still be a useful method to identify unknown compounds, such as drugs or fibers.

Phase contrast

Specimens that demonstrate small optical path, or phase differences, such as glass, are amenable to analysis by phase contrast microscopy. These phase differences are imaged using half-silvered rings and disks placed in the optical system to convert phase differences into amplitude differences, which are more easily observed. In the example of glass specimens, very accurate measurements of the refractive indexes of known and questioned samples can be made, with significant measurements to 0.00002. A hot stage is mounted on a compound microscope outfitted for phase contrast work. The glass specimen is immersed in a special silicon oil; as the temperature increases, the refractive index of the silicon oil decreases while that of the glass remain more or less the same. The difference in amplitude between the glass and the oil is easily seen; in fact, commercial off-the-shelf instrumentation is available that automates the process, using image analysis to determine the differences.

Fluorescence

Luminescence can be subdivided into phosphorescence, which is characterized by long-lived emission, and fluorescence, in which the emission stops when the excitation stops. The wavelength of the emitted fluorescence light is longer than that of the exciting radiation. In other words, a radiation of relatively high energy falls on a substance. The substance absorbs and/or converts (into heat, for example) a certain, small part of the energy. Most of the energy that is not absorbed by the substance is emitted again. Compared with the exciting radiation, the fluorescence radiation has lost energy and its wavelength will be longer than that of the exciting radiation. Consequently, a fluorescing substance can be excited by near-UV invisible radiation and its fluorescent components (fluorophores) are seen in the visible range. In a fluorescence microscope, the specimen is illuminated with light of a short wavelength, for example, ultraviolet or blue. Part of this light is absorbed by the specimen and re-emitted as fluorescence. To enable the comparatively weak fluorescence to be seen, despite the strong illumination, the light used for excitation is filtered out by a secondary (barrier) filter placed between the specimen and the eye. This filter, in principle, should be fully opaque at the wavelength used for excitation, and fully transparent at longer wavelengths so as to transmit the fluorescence. The fluorescent object is therefore seen as a bright image against a dark background.

Glossary

Backscattered electrons Electrons that have undergone inelastic scattering and contain information about the sample's average atomic number.

Energy-dispersive spectrometer (EDS) An instrument that detects the number and energy of x-rays emitted

from a sample excited by an electron beam, thus identifying the sample's elements and its composition.

Interaction volume The portion of the sample affected by the primary electron beam of the instrument.

Introduction

Electron microscopes use beams of electrons to create magnified images of specimens, either in transmission, with the beam passing through an extremely thin sample, or of their surface, with the beam scanning across the sample. The advantages to using an electron microscope are many, including the following:

- A resolving power of better than 50 pm in transmission and about 1 nm for scanning, because of the extremely short wavelength of electrons (about 100 000 times shorter than photons)
- Magnifications of up to 10 000 000 $\times$ in transmission and 500 000 $\times$ for scanning
- Varied equipment that can be attached to the microscope, allowing analytical imaging as well as elemental, chemical, and crystallographic analysis

Instead of ground glass lenses as in the light microscope, an electron microscope uses electromagnets as 'lenses' to focus the beam into an image and to control its position on the sample. The beam of electrons is generated by a filament of various types, including tungsten or lanthanum hexaboride (LaB₆), heated by a high-voltage anode (up to 300 kV). The filament emits electrons by thermionic or field emission that are then formed into a beam by the lenses. The charged nature of the electron beam necessitates that the samples be conductive, otherwise charges will build up on the sample and obscure the image by deflecting or temporarily disrupting the beam. Coating nonconductive samples with a thin layer of gold/palladium or carbon typically makes samples suitably conductive. The entire columnar structure of the conventional electron microscope is under high to very high vacuum internally, at least 10⁻⁴ Torr, as air molecules would deflect the electrons. The vacuum requires specialized sample preparation, particularly for biological samples, to render them fixed, dehydrated, and stable under vacuum. Low-pressure electron microscopes are commercially available that can work at normal air pressure or increased pressures. Because the sample is imaged with electrons, rather than with photons in optical microscopy, no color information about the sample is communicated and images are presented in grayscale.

In a transmission electron microscope (TEM), the electron beam passes through the sample and is differentially diffracted

by the sample's internal structures. The magnified (real) image is viewed on the microscope's computer screen or recorded (film or digital). For the electron beam to pass through the sample, the sample itself must be extremely thin (about 100 nm) – a major disadvantage of the instrument. Samples for TEM imaging are dehydrated, chemically fixed, and embedded in a polymer to support them; they are then sliced to the correct thickness using an ultra-microtome. Outside of pathology, TEMs are rarely used in conventional forensic science work.

Scanning electron microscopes (SEMs; [Figures 1 and 2](#)) are far more common in forensic laboratories than TEMs. SEMs use essentially the same mechanisms for beam generation but the lenses control the beam very differently than in a TEM. The electron beam is initially focused by condenser lenses, which reduce the beam to a spot a few nanometers in diameter. One or more pairs of electromagnetic scanning coils deflect the beam so that it scans a rectangular surface of the sample in a raster (x and y coordinates). The size and rate of the scan can be adjusted by the user through a computer in the instrument chassis. The key utility of the SEM is the beam-sample interaction and the energy exchange between them. The primary electron beam (1°) interacts with the sample in a teardrop-shaped volume (called the interaction volume), the size of which is dependent upon, among other factors, the 1° beam's energy, the 'spot size' (the diameter of the beam and its scan rate), the average atomic number of the sample, and the sample's density; the depth of the interaction volume can range from 100 nm to as much as 5 μ m ([Figure 3](#)). The interaction volume yields a range of energy types, all of which provide different kinds of information about the sample and its content.

- *Inelastic scattering*: Secondary electrons (2°) and surface information
- *Elastic scattering*: Backscattered electrons (BSE) and atomic density images
- *Electromagnetic radiation*: x-rays and elemental content
- *Other*: Cathodoluminescence (CL); backscattered crystallographic patterns (Kikuchi patterns)

The SEM chamber typically is quite small, particularly with additional analytical instrumentation attached to it; images and information from the SEM and its attendant instruments

Figure 1 A diagram of a scanning electron microscope (SEM).

Figure 2 A scanning electron microscope (SEM).

are displayed on screens (Figure 4). The scanning function of the microscope provides for detailed positional information about the sample's content, such as elemental or compositional maps, when coupled with analytical instrumentation, such as BSE and energy-dispersive x-ray detectors. SEMs can produce magnifications from $2\times$ up to $500\,000\times$, making it a versatile instrument for biological and materials analysis.

Figure 3 The beam-sample interaction volume.

Additional Instrumentation for Electron Microscope Applications

Visualizing a specimen may be a useful component of a forensic analysis but with a SEM, it is only the start of what is analytically possible. The multiple energy types that the sample yields – as listed earlier – provide a broad range of potential data to help categorize and compare specimens.

Beyond imaging the surface of the specimen with secondary electrons, atomic number information can be gained by using a backscattered electron detector (BSED). BSEs act like billiard balls colliding with large objects, in this case, atoms. The larger the atom, the greater is its atomic number (designated as Z), which leads to a greater cross-sectional area, and, therefore, the higher the probability of elastic collisions. These BSEs reach the detector in proportion to the mean atomic number of the specimen; on the image, the brighter the area, the higher is the mean Z . BSE images are useful for relative compositional imaging and locating areas of potential analytical or structural interest, despite the fact that BSEs carry almost no topographic

Figure 4 The sample chamber of an SEM and the instrument computer console.

Figure 5 A backscattered electron (BSE) image of a fire brick, with intensity of grayscale, indicates proportionately greater atomic number values (Z).

or quantitative elemental information (Figure 5). For example, in gunshot residue (GSR) analysis, bright particles of high mean Z are more likely to have elements characteristic of GSR, like lead ($Z=82$), antimony ($Z=51$), and barium ($Z=56$). The BSED converts the particles' mean Z to brightness and the instrument's computer converts that signal into a threshold value for detection; particles with a brightness above a certain value (i.e., above a certain mean Z) would then be detected and analyzed for their elemental content, determining whether or not they are GSR. Because of their proportion of the interaction volume, BSEs 'spread' farther than secondary electrons and thus carry less precise spatial information.

That elemental content information comes from x-rays emitted by the sample when it is struck by the 1° electron beam; those x-rays are detected either by their energy or wavelength. The 1° electron beam excites the inner shell electrons in the sample's atoms. These electrons are ejected from the inner shell and their vacancy filled by electrons from a higher energy outer shell; the residual energy, as radiation, is emitted from the sample. This differential energy is characteristic of the atoms' shell energies and identifies the atoms (elements) by their reaction(s) to the beam (Figure 6). An energy-dispersive spectrometer (EDS) detects the number and energy of the x-rays, thus identifying the sample's elements and its composition. All x-rays produced by the sample interaction are detected simultaneously, providing a comprehensive spectrum of detection. Complex software can combine the positional information of the 1° electron beam's raster with the elemental compositional information and produce a wide variety of analyses, such as quantitative and phase distribution analysis, and visualizations, such as elemental maps. Additional software, coupled with a computerized SEM stage, can conduct unattended search and analyze procedures, such as automated particle analysis. The theoretical detection limit for EDS is about 0.08% wt with a quantitative resolution of about $\pm 1\%$; the effects of surrounding elements (the 'matrix') may worsen these values.

Figure 6 Energy-dispersive interactions yielding elemental information.

The other type of x-ray detector measures not the energy of the x-rays but their wavelength. The sample's x-rays are collimated and focused on a single crystal at a precise angle. The elements are detected as the x-rays are diffracted by the crystal; the spacing of the x-ray's waves and the crystal's lattice (d-spacing) are related by Bragg's law and produce constructive interference if they satisfy Bragg's law. For example, iron (Fe) emits a $K\alpha$ x-ray at 6.4 keV (kiloelectron volts) with $\lambda = 0.0001937 \mu\text{m}$ and its detection would require a lithium fluoride (LiF) crystal which has a d-spacing of $0.0002014 \mu\text{m}$. One crystal can detect one wavelength and thus one element; this limitation is offset by nearly one order of magnitude decrease in detection limit (0.01% wt, or between 10 and 100 ppm) and an increase in quantitative precision. Wavelength dispersive spectroscopy (WDS) detectors cannot detect elements below boron ($Z=5$). One WDS detector, however, can contain four or five crystals with differing properties and the detector can automatically move between crystals, allowing for the entire periodic table to be scanned (above boron) but only one element at a time. Combined with an EDS detector on the SEM (to determine the general chemical composition and if the element of interest is present), WDS detectors provide a comprehensive suite of methods for elemental analysis.

CL occurs when the 1° beam interacts with a luminescent material; the material may produce visible light that provides information about the composition and quality of the material. When the 1° electron beam strikes the sample, electrons may be promoted from the valence to the conduction band, creating a hole. If the hole is filled by an electron, a photon may be emitted; the energy of the photon (related to its color) relates to the material's content, composition, and structure. Almost any nonmetallic material can be analyzed by CL, including ceramics, gemstones, minerals, and glasses. An increased interest in forensic applications of CL has emerged in the last few years as the technology has advanced.

Forensic Applications of SEM

The SEM is a versatile instrument, capable of visualizing and analyzing almost any material; this makes it a perfect 'workhorse' piece of equipment for a forensic laboratory. The applications for SEM-EDS are innumerable. SEM, typically in conjunction with EDS, has been applied to forensic research and cases involving paint, GSR, glass, metals, bone, minerals, soils, construction materials, dental restorations, pollen, duct tape, cut marks, and explosives, among many others in the literature. The instrument's ability to visualize a surface, position the beam for analysis, and generate elemental and chemical information about heterogeneous components of a sample make the SEM-EDS invaluable to forensic investigations.

A few examples may help demonstrate the diverse utility of this instrument. In an attempt to identify bullet wipe from wounds, pork ribs with intact muscle tissue were shot with 0.45 caliber ammunition from distances of 1–6 ft. Unexpectedly, GSR was found deep in the wound tract, inside the bone, even though the shot was fired from 6 ft away, and after processing the tissue and bone for viewing in a conventional SEM. This finding means the analyst has the potential to differentiate gunshot trauma from other, confounding types of

trauma by this method. The ability to visually find and elementally identify individual particles of GSR – only a few microns across – would not be possible with any other method.

In another example of wound evaluation, an SEM was used to visualize toolmarks in bone and compare them. Bone and its attendant tissues are excellent media for receiving and recording toolmarks, such as those made by knives, and allow for traditional toolmark comparisons. Additionally, directionality can be ascertained as well as whether the cut was made when the bone was fresh or dried – an important distinction in forensic investigations.

SEM-EDS is also extremely useful for the analysis of post-blast trace evidence materials, typically collected from items in the blast area by swabbing. In the 2002 Bali bombings, which killed 202 people, explosive residues were collected from the pitting in the soft aluminum of street signs that had been blown onto nearby rooftops because of the explosive force of the blast. These residues helped to reconstruct the bomb manufacturer's activities and link them to the scene.

In another example of enhanced analytical ability offered by the SEM, researchers were able to identify and differentiate most automotive body fillers, which are sometimes encountered as evidence in hit-and-run accidents. Based on chemical and physical characteristics, SEM-EDS was able to classify the body fillers in the study into four groups and further differentiate 13 samples, making SEM-EDS the single best discriminatory method.

Glossary

Color test A chemical test where a reagent or a series of reagents is added to a specimen or specimen extract and produces a color if a substance or a class of substances is present.

Conway microdiffusion cell A porcelain dish containing either two or three concentric reservoirs with an accompanying glass color.

Microcrystalline test A chemical test where the addition of a reagent or reagents produces crystals of

characteristic shapes or colors observable under a microscope.

Protein precipitation A chemical process where a reagent is added to a biological specimen to remove protein from the specimen.

Thin-layer chromatography A technique whereby components of a specimen mixture are separated based on differences in solubility between a stationary phase coated on a plate and a mobile phase present as vapors in a development tank.

Introduction

A wide range of evidence types may be presented to a forensic chemistry laboratory for analysis. This includes drug-related materials such as powders, liquids, tablets, capsules, plant material or solutions, and paraphernalia such as syringes, cookers, spoons, cigarettes, and pipes. Explosives evidence can include both unexploded bulk material and postblast residues on debris. Although some of the components of the evidence may be suggested by external appearance, the forensic chemist is still required to perform analytical testing on the submitted evidence. For example, drug-related evidence will usually contain 'active' drug or drugs as well as inactive substances used to dilute the potency of the preparation. As the workload of the forensic chemist increases, it would be impractical to subject all submitted evidence to sophisticated and time-consuming extraction and instrumental techniques. Therefore, there is the need for a battery of relatively simple screening tests that the chemist can perform to assist in an ultimate identification.

The forensic toxicologist frequently faces the same challenges that the forensic chemist encounters. For instance, in postmortem cases, death may occur from exposure to one or more toxic substances. Most of the cases involve alcohol and therapeutic or abused drugs, but other cases may involve gases, volatile substances, pesticides, metals, or environmental chemicals. The postmortem forensic toxicologist must be equipped to assist the medical examiner or coroner in the investigation of death due to any of the above substances. In a 'general unknown' case, most toxicology laboratories perform a series of tests designed to screen for a large cross-section of substances that would reasonably be encountered. Many of these tests are designed to detect or rule out a class or classes of drugs.

One of the oldest analytical procedures used by forensic chemists or forensic toxicologists is broadly classified under 'color tests.' Color tests or spot tests are chemical tests that involve the reaction of a sample with a reagent or a series of reagents to produce a color or a change in color. The biggest

advantages to color tests are their simplicity and ease of use. No sophisticated equipment is required and the time needed to train analysts is short. A negative result for a color test is helpful, for example, in excluding a drug or a class of drugs, depending on the test performed. It is interesting to note that many of these color tests were developed empirically. The chemistry behind these color tests is often complex or unknown.

A chemical test with greater specificity than the color test is the microcrystalline test. To perform a microcrystalline test, a drop of reagent is added to a small quantity of sample on a microscope slide. After the reaction is complete, crystals with unique size and shape develop in relation to the substance present. Although these tests can be performed directly on the powder, the presence of dilution agents may change the structure of the crystals.

It must be emphasized that all chemical tests must be confirmed by an alternate analytical technique, based on a different chemical principle. In the forensic chemistry laboratory, the confirmatory test usually includes infrared spectrophotometry or mass spectrometry. In the forensic toxicology laboratory, gas chromatography/mass spectrometry or liquid chromatography/mass spectrometry are currently the methods of choice for confirming the presence of most drugs.

It is beyond the scope of this article to include all the chemical tests available to the forensic chemist or toxicologist. Instead, many of the currently used or historically important tests are covered. Presumptive tests for serological evidence (blood and semen) are dealt with elsewhere.

Chemical Tests on Drug Evidence

Color Tests

There are a large number of color tests that have been developed over the years to screen for the presence of certain drugs or drug classes. Many of these tests are commercially available as kits for use in the field, utilizing ampoules of reagent that are crushed after addition of a small amount of test material to a

small plastic sachet. This helps to avoid any contact with the often harmful chemicals used in the tests. The following is a list of some of the more common color tests:

Dille–Koppanyi test: Two reagents are required for this reaction: (1) 1% cobalt acetate and 2% glacial acetic acid in methanol and (2) 5% isopropylamine in methanol. After sequential addition of the two reagents, a violet color is obtained with imides in which the carbonyl and amine are adjacent in a ring. This would include barbiturates, glutethimide, and saccharin. No color reaction occurs when there are substituent groups on the nitrogen atom.

Duquenois–Levine test: Two reagents and chloroform comprise this reaction. The first reagent added is a mixture of 2% vanillin and 1% acetaldehyde in ethanol and the second reagent is concentrated hydrochloric acid. A blue-purple color indicates cannabis, coffee, or tea. Cannabis may be differentiated from the other substances by extracting with chloroform. If the purple color enters the chloroform layer, then the test is presumptively positive for cannabis.

Ehrlich's test: The addition of 1% *p*-dimethylaminobenzaldehyde in 10% hydrochloric acid in ethanol to a sample containing ergot alkaloids yields a violet color. This serves as a rapid screening test for lysergic acid diethylamide (LSD). In addition, the presence of psilocin is indicated by a blue-gray color.

Liebermann test: The reagent is prepared by adding 5 g of sodium nitrite to 50 ml sulfuric acid. A number of colors, from orange to orange-brown to yellow, are produced. Different structures are suggested by the color. The test needs to be repeated with sulfuric acid alone as many compounds produce color changes with the acid.

Mandelin test: This is another reaction that produces a wide array of colors and must be interpreted in light of the Liebermann test. The reagent is 1% ammonium vanadate in sulfuric acid.

Table 1 lists the colors produced by common drugs with both the Liebermann and the Mandelin tests.

Marquis test: This reagent is prepared by adding 1 ml of 40% formaldehyde to 100 ml of concentrated sulfuric acid. Adding one drop of this reagent to the sample may give rise to a

multitude of colors. Structures that give a violet color include a ring sulfur, a ring oxygen, or aromatic compounds consisting entirely of carbon, hydrogen, and oxygen. Heroin, morphine, and most opioids produce a violet color. Amphetamine and methamphetamine produce an orange-brown color with this reagent. **Table 2** lists a number of drugs and the colors generated with this reagent.

Scott test: This is a series of color reactions used to screen for the presence of cocaine. Two percent cobalt thiocyanate in water and glycerine (1:1) will cause a powder containing cocaine to turn blue. The addition of concentrated hydrochloric acid converts this color to a clear pink. The blue color reappears upon extraction with chloroform.

Microcrystalline Tests

It is recommended that a polarizing microscope be used for the microcrystalline tests. The best magnification for observing crystals is approximately 100 $\times$. The description and classification of microcrystals can be a complex process. When a reagent is added to different substances, differences in shape, color, or dichroism may result. The following is a general description of some of the shapes that may be encountered when performing microcrystalline tests. These descriptions are based on the classification of Fulton in *Modern Microcrystal Tests for Drugs*.

- **Bars:** Solid appearing crystals with three unequal dimensions
- **Blades:** Thin flat crystals with much greater length than width
- **Grains:** Granular precipitate without distinction at 100 $\times$ magnification, or crystals that have approximately the same length, width, and thickness
- **Needles:** Crystals with little width or thickness in comparison to length
- **Plates:** Thin flat crystals with width comparable to length
- **Rods:** Solid appearing crystals with greater length than width or thickness; width and thickness are significant and equal in magnitude
- **Rosettes:** Aggregate of crystals that grow out from a central point in all directions
- **Tablets:** Flat crystals with similar length and width greater than thickness

Table 1 Color reactions of some common drugs with Liebermann's and Mandelin's reagents

Drug	Color	
	Liebermann's	Mandelin's
Amphetamines	Red-orange	
Codeine	Black	
Diphenhydramine	Brown-orange	Yellow
Glutethimide	Red-orange	
LSD		Gray
Meperidine	Red-orange	
Mescaline	Black	Orange-yellow
Methadone	Brown-orange	Green to blue
Methylenedioxymphetamine (MDA)	Black	Green to blue
Morphine	Black	Blue-gray
Phenmetrazine	Red-orange	
Propoxyphene	Brown	Gray-brown
Psilocybin		Green

Table 2 Drugs that react with the Marquis reagent

Drug	Color
Amphetamine	Orange-brown
Aspirin	Pink
Codeine	Purple
Diphenhydramine	Yellow
Fentanyl	Orange
Heroin	Purple
Meperidine	Orange
Methamphetamine	Orange-brown
Morphine	Purple
Opium	Purple
Propoxyphene	Black
Psilocybin	Yellow

Table 3 Common microcrystalline reagents

Chemical	Symbol
Bromauric acid	HAuBr ₄
Chlorauric acid	HAuCl ₄
Chloroplatinic acid	H ₂ PtCl ₆
Iodobismuth acid	H ₃ BiI ₆
Mercuric chloride	HgCl ₂
Mercuric iodide	HgI ₂
Potassium iodide	KI
Potassium permanganate	KMnO ₄
Silver nitrate	AgNO ₃

Table 4 Examples of microcrystalline tests for commonly abused drugs

Drug	Reagent(s)	Crystals
D-amphetamine	5% HAuBr ₄ in (1+2) H ₃ PO ₄ + 1(2+3) H ₂ SO ₄	Light-colored trapezoidal blades
Cocaine	20% HOAc	Long rods with short arms at right angles
Heroin	5% HAuCl ₄ in H ₂ O	Rosettes of needles
D-methamphetamine	5% HgCl ₂ in H ₂ O	Orange needles
	H ₃ BiI ₆ in (1+7) H ₂ SO ₄ , hanging drop	
Phencyclidine	10% KI in water	Branching needles

H₃PO₄ phosphoric acid; H₂SO₄, sulfuric acid; HOAc acetic acid.

Besides a general shape, crystals will often have a characteristic angle of form that may be measured. In addition, crystals will often display dichroism or two different colors with different orientation of polarized light. Although additional colors may be seen, they are usually gradations of the two extreme colors. Undoubtedly, the best description of crystal forms for a particular test is via a photograph. Furthermore, the unknown crystals should be compared to crystals obtained with actual standard material.

Another factor in the type of crystals formed is the reagent or reagents used to generate the crystals. Table 3 lists some of the most common reagents used. The solvent in which these reagents are dissolved also is a significant factor in the types of crystals produced. The general medium for these tests is water. Several aqueous acids have been used most commonly as solvents, including phosphoric acid, sulfuric acid, hydrochloric acid, and acetic acid. These acids alter solubility characteristics of the crystals. For example, phosphoric acid produces the greatest insolubility while acetic acid yields the greatest solubility.

Although the use of microcrystalline tests in forensic chemistry has diminished over the years with the availability of more advanced instrumentation, there are a number of tests that are still in use for commonly seized substances. Table 4 lists a common test for some of these substances.

Chemical Tests on Explosives Evidence

Chemical analysis is an essential element of investigations into any incidents involving explosives. The information that can

Table 5 Presumptive color tests for explosives

Test	Target explosives	Color change
Alcoholic KOH – 3% KOH in ethanol	Trinitrotoluene (TNT)	Purple/brown
	2,4-DNT	Yellow
	2,6-DNT	
	Tetryl	Violet
Griess reagent – methanolic <i>N</i> -(1-naphthyl) ethylenediamine in the presence of sulphanilic acid and zinc dust	Nitrates and nitrites	Purple
	Nitrate	Pink to red
	Nitrocellulose	Pink
	Nitroglycerin	Pink to red
	Pentaerythritol tetranitrate (PETN)	Pink to red
	Research development explosive (RDX)

be gained concerning the type of explosive, quantity, and bomb architecture is vital for successful apprehension of the perpetrators. Presumptive color tests are important in chemical analysis of postblast debris as they can provide this information at an early stage in the investigation. This is extremely helpful in rapid identification of suspects. The color tests allow subsequent confirmatory testing to be more targeted, thus providing more timely and efficient analysis of the evidence. An example of their use in an investigation can be found in the Bali bombing case study listed in the section 'Further Reading.'

Commonly used color tests for explosives are outlined in Table 5. These tests are rapid and allow of quick screening of large quantities of debris in order to isolate samples that show promise for future analysis. In a similar fashion to the tests for drugs, many of these reagents are available as commercial kits that can be used close to the crime scene (see Figure 1). Any samples that provide promising results are forwarded for confirmatory analysis in the laboratory with identity being established through corroboration by two independent techniques (so called 'orthogonal testing').

Presumptive tests for explosives can also be used to aid in other ways with investigations. An interesting example of their

use in the apprehension of a suspect thought to have planted an improvised device on a crowded beach can be found in the section 'Further Reading'. The bomb had been based on the explosive Semtex and was disguised as a packet of cigarettes that had been carried to the beach under the waistband of the suspect's bathing suit. There were sufficient traces of the explosive on his skin to be detected using a presumptive chemical test (see Figure 2). However, caution must be applied when using presumptive tests in this fashion, as demonstrated by the issues raised in the IRA terrorism cases of the 1970s (see *R v Maguire and others* (1992) 94 Criminal Appeal Reports 133 and *R v Ward* (1993) 96 Criminal Appeal Reports 50 for details).

Chemical Tests on Biological Specimens

Most of the color reactions used in the past have been replaced by immunoassay or chromatographic screening. Nevertheless, there are some color tests that remain in use. Some biological

Figure 1 Explosives Testing Kit (ETK). Each of the colored tubes detects a different family of explosives. Reproduced from Almog J (2006) Forensic science does not start in the lab: The concept of diagnostic field tests. *Journal of Forensic Sciences* 51: 1228–1234, with permission from John Wiley & Sons. specimens are amenable to presumptive chemical tests without any specimen pretreatment. For instance, color tests can often be performed directly on urine or stomach contents. Other specimens, such as blood, bile, liver, and kidney, require some type of pretreatment before the chemical test. Although liquid–liquid extraction or solid-phase extraction can precede the chemical test, there are simpler separation techniques that are more 'appropriate' given the presumptive screening nature of these tests. Two such separation techniques are Conway microdiffusion and protein precipitation.

A Conway microdiffusion cell is a porcelain dish containing either two or three concentric reservoirs with an accompanying glass cover. A trapping reagent is added to the center well. As the name implies, the trapping reagent captures the analyte of interest for the subsequent chemical reaction. In some situations, the trapping reagent is the chemical reagent. In a two-reservoir well, the blood or tissue specimen is added to the outer well, followed by the releasing agent. This releasing agent causes the analyte to leave the biological sample. A glass cover is rapidly placed over the cell, which is then swirled for a brief time. The reaction then proceeds at room temperature for several hours. The glass cover is usually greased to prevent the release of analyte from the cell. Alternatively, a three-well cell can be used. The sample and releasing reagent are added to the middle well, while a sealing agent is added to the outer well. After the reaction is complete, the center well contains the trapped analyte.

Protein precipitation is another simple pretreatment technique. The protein content of human body fluids and tissues is considerable, from about 6% by weight in plasma to greater than 50% by weight in liver and other organs. Numerous reagents have been developed to precipitate protein; two that are commonly used in drug analysis are trichloroacetic acid (10–15% in water) and tungstic acid (10% sodium tungstate in water and used in conjunction with 3N sulfuric acid). Once the proteins have been precipitated, separation of aqueous and solid proteins must occur by filtration or centrifugation.

A number of color reactions have been devised to identify either a number of drugs within a particular drug class or a particular substance. Many of the color reactions on drug classes are used in conjunction with thin layer chromatography. Once the individual substances have been separated on the thin layer plate, these color reagents are applied to the plate for visualization of color. Interpretation of color tests for drug classes must be done with caution. Drugs within a class may have therapeutic ranges that differ by orders of magnitude. This means that a negative result may not exclude the presence

Figure 2 Explosive Testing Kit testing for explosives traces on suspect's stomach. Left: sampling; right: positive response for nitrate- and nitramine-type explosives. Reproduced from Almog J (2006) Forensic science does not start in the lab: The concept of diagnostic field tests. *Journal of Forensic Sciences* 51: 1228–1234, with permission from John Wiley & Sons. Copyright © 1999–2012.

of a drug, while a positive test does not necessarily mean that a toxic amount of drug is present. Some color tests that may still be used for biological specimens are described below:

Acetaminophen: The test for acetaminophen is performed on urine or a protein-free filtrate of blood and requires heating at 100 °C after the addition of hydrochloric acid. A blue color after the addition of 1% *o*-cresol in water and ammonium hydroxide constitutes a positive test for acetaminophen. Therapeutic or toxic use of acetaminophen can be identified using this color reaction.

Carbon monoxide (CO): One of the early methods of CO analysis involved microdiffusion using a Conway cell. The specimen is placed in the outer well and sulfuric acid is added to release the CO from the hemoglobin. A solution of palladium chloride is added to the center well. The cell is sealed and incubated at room temperature for 1–2 h. As the reaction proceeds, the palladium chloride is reduced to metallic palladium, forming a black or a silver mirror in the center well, and the CO is converted to carbon dioxide. This method is capable of distinguishing between normal (<10%) and elevated carboxyhemoglobin saturation levels.

Cyanide: In a two-reservoir well of a Conway microdiffusion cell, the blood or tissue specimen is added to the outer well, followed by the releasing agent. This releasing agent may be a dilute mineral acid such as sulfuric acid, or it may be an organic acid such as tartaric acid. The releasing agent causes the formation of the gaseous hydrocyanic acid (HCN). To the center well is added dilute base. This serves as a trapping reagent for the released HCN. The glass cover is rapidly placed over the cell, which is then swirled for a brief time. The reaction then proceeds at room temperature for several hours. Alternatively, a three-well cell is used. The sample and acid are added to the middle well, while a more dilute acid is added to the outer well. This acts as a sealing agent. After the reaction is complete, the center well contains the trapped CN and is available for detection. A number of colorimetric reactions have been developed to detect CN from the trapping agent. One classical color reaction uses chloramine-T to convert CN to cyanogen chloride. A color reagent containing pyridine and barbituric acid is then added to produce a red color. Another common color reagent uses *p*-nitrobenzaldehyde and *o*-dinitrobenzene, which, when added to the trapping agent, produces a violet color.

Methanol: A color test specific for methanol involves the oxidation of methanol to formaldehyde by 3% potassium permanganate. Sodium bisulfite and chromotropic acid are then added, followed by a layering of concentrated sulfuric acid. A purple color at the acid/filtrate interface is a positive test. The test needs to be repeated without the addition of permanganate to rule out the presence of formaldehyde in the specimen.

Salicylate: Salicylate, the metabolite of aspirin, reacts with an acidic solution of ferric chloride to produce a purple color. This color reaction requires the presence of both the free phenolic group and the free carboxylic acid group that appears on the salicylate molecule. Therefore, aspirin itself will not produce a positive result before hydrolysis to salicylate. This color test has sufficient sensitivity to detect therapeutic use of salicylate.

Glossary

Derivatization Use of a chemical reaction to convert analyte into a form that may be more detectable or amenable to separation.

Enantiomers A pair of chemical compounds whose molecular structures are non-superimposable mirror images of each other.

Ion mobility spectrometry Instrumental analytical technique based upon separation via differential migration of gas phase ions through an electric field.

Liquid–liquid extraction Transfer of a dissolved substance from one liquid phase to another immiscible (or partially immiscible) liquid in contact with it.

Solid-phase extraction The separation method by which compounds adsorbed on a solid phase are preferentially removed by use of a suitable solvent. Processes involved are essentially chromatographic in nature.

Introduction

Many types of evidence that are encountered in the forensic science laboratory consist of complex mixtures of substances. The complexity of these materials is a double-edged sword to the forensic scientist. The more complex and variable a mixture, the greater is its probative value when comparing known and questioned samples. However, complex mixtures also create analytical problems, as most compounds need to be relatively pure in order to be identified by analytical techniques, such as spectroscopy. While chromatographic and electrophoretic separations are used widely in forensic science, other separation techniques are also important. These can be used both to clean up samples before analysis and for determining useful information about the sample of interest. This article provides an overview of nonchromatographic/electrophoretic separation techniques that are often encountered in forensic analysis.

Physical Separations

Physical separations are commonly used in forensic chemistry. Examination of a mixture under a stereoscope may yield variation of its component particles. These particles may vary in their shape, size, color, opacity, texture, or other physical properties, which can be observed microscopically. The particles may then be physically separated from the mixture. Particle selection or ‘picking’ is the major separation technique used in most areas of trace evidence. A skilled examiner can recognize and pick out critical particles in explosive residue. Paint examiners can select uncontaminated particles out of a mixed smear of paint for examination and comparison. This type of separation can also be utilized in mixtures containing cocaine hydrochloride. This salt form of cocaine has a translucent, shale-like appearance, which can be easily distinguished from the coarse grains of most diluents and excipients used as cutting agents in cocaine mixtures.

Forensic geologists have long used particle size to separate soil components for analysis. A novel example of this is the use of a mesh screen for separation of sand grains onto an SEM stub for automated elemental analysis and mineral identification (Figure 1). Manual separation of particles should always be explored before attempting a chemical separation.

Volatile Materials

Volatile materials are often present in drug and fire debris cases submitted to forensic laboratories. These materials (primarily solvents and flammables) can be easily separated from relatively nonvolatile substances by techniques such as distillation, sublimation, absorption–elution, and solid-phase microextraction (SPME).

Distillation and sublimation are the techniques occasionally used in analysis of drugs. Amines, such as amphetamine and methamphetamine, are relatively volatile and can be flash distilled to separate the drug from a complex mixture. Dimethylsulfone is currently one of the most common cutting agents used with methamphetamine in the United States. It is far more volatile than methamphetamine, sublimating at 35–38 °C (90–100 °F). It can be easily removed from methamphetamine by placing the mixture on a watch glass and sublimating the dimethylsulfone over a steam bath. The purified methamphetamine can then be analyzed via infrared spectrometry.

Examination of fire debris for the presence of ignitable liquids (e.g., petrol, kerosene, and diesel) requires that the residual amounts of these liquids be separated from the debris. Samples of debris are sealed into airtight nylon bags or paint cans and heated to volatilize the ignitable liquid into the headspace of the container. The vapor in the headspace can then be analyzed directly by removing a portion with a syringe. Often the concentration of the volatile material in the headspace is insufficient for direct analysis. In these cases, a process known as absorption–elution can be used to concentrate the volatile species. In this process, the volatiles are absorbed by a

Figure 1 Photograph of sand particles separated using a mesh screen and mounted on an SEM stub. Courtesy McVicar MJ and Graves WJ (1997) The forensic comparison of soils by automated scanning electron microscopy. *Journal of the Canadian Society of Forensic Science* 30: 241–261.

material (usually activated charcoal) and then extracted from the absorbent in a concentrated form by a solvent. The process of absorption can be active or passive. In active or dynamic absorption, the material containing the volatile species is heated and the vapor forced through a vessel containing absorbent. A typical setup may consist of charcoal housed inside a disposable pipette or hypodermic needle connected to a vacuum pump. The open end of the vessel is placed in the headspace of the sample and the air containing the ignitable liquids is drawn through the vessel. The charcoal would then be removed for solvent extraction of the captured volatile substances (elution). Passive absorption entails placing the absorbent material directly inside the airtight container while heating to volatilize the ignitable liquids. Vaporized molecules of the volatile species contact the absorbent in a random fashion. Because the volatile compounds are not forced to contact the absorbent, the time of exposure of the absorbent to the vapor must be dramatically increased in order to ensure proper absorption.

SPME is a relatively recently introduced technique that is being used increasingly in forensic chemical analysis. This technique is based around a special syringe containing a spring-loaded fiber coated with a bonded phase. The fiber in the syringe can be extended and retracted. The sample containing the volatile compounds is sealed in an airtight container. The syringe is then inserted into the headspace of the container and the fiber extended and exposed. The container is heated for a period of time to release the volatile species into the headspace. The volatile substances are adsorbed onto the fiber, which is then retracted into the syringe. The syringe is then used for injection into a gas chromatograph. The fiber is extended from the syringe into the injector port and the heat of the injector port desorbs the volatile species from the fiber

Figure 2 Photograph of an SPME fiber inserted into headspace of a sampling vial. (Courtesy R Mindrup, Supelco Inc.).

(Figure 2). SPME may also be used to concentrate analytes from a liquid solution onto the SPME fiber. A variety of bonded phase chemistries are commercially available allowing manipulation of selectivity. This technique is increasingly being used in the areas of solvent, drug, fire debris, and high-explosives analysis.

Chemical Separations

Solvent Extraction

Although chemical separations have increasingly become chromatographic in nature, solvent extraction is still frequently used in the forensic laboratory, especially in drug analysis, where chemical separations are generally followed by confirmatory qualitative techniques such as infrared spectrometry. Solvent extractions can be either single-phase or multiphase in nature. The theory and process of both types of solvent extractions are based on many criteria, the most important of which is solubility.

In a single-phase extraction, components of a mixture are separated based on the solubility of the components in a solvent. In this type of extraction, solvent selection is critical. The target component of the mixture must either be soluble in the solvent, while all remaining components are insoluble, or vice versa. The solvent is added to the mixture and then filtered to separate undissolved solute and solvent. If the target compound is soluble in the solvent, it is then recovered by evaporation of the solvent. If the target compound is insoluble in the solvent and the other components are soluble, the filter paper is then dried and the material is recovered. This process is also

known as 'solvent washing.' In complex mixtures, it is usually not possible to find a suitable single solvent to separate all components of the mixture. If this is the case, several solvents are selected and applied in a serial manner to effect the separation. The selection of solvent generally proceeds from the solvents in which few compounds are soluble (hexane and ether) to those in which a moderate number are soluble (acetone, dichloromethane, and chloroform) to those in which most substances are soluble (alcohols and water). Use of acidified or basified solvents may increase the specificity of the extraction.

In multiphase or liquid-liquid extractions, components of a mixture are separated based primarily on their solubility in two immiscible solvents. The mixture to be separated is added to a solvent (generally aqueous) and second solvent (usually organic) is then added. The components of the mixture then partition into the solvent or solvents in which they are most soluble. This type of extraction is extremely flexible as solvent components can be selected, mixed, their pH changed, heated or cooled, used in vastly different proportions, and so on, to effect the desired separation. The most commonly modified variable in multiphase extractions is the pH of the aqueous solvent phase, which is varied by addition of strong acids or bases. The solubility of components dissolved in this phase is directly affected by these pH changes. By adjusting the pH of the aqueous phase to make a particular analyte relatively insoluble in the aqueous phase, the stage is set for the analyte to be extracted into the second solvent, which is then added.

Drugs, in particular, are amenable to separations based on changes of pH in multiphase extractions, lending to a terminology based on their behavior on extraction. 'Acidic drugs' are relatively insoluble in acidic solutions and may generally be extracted from acidic aqueous solutions into an organic solvent. 'Basic drugs' are

relatively insoluble in basic solutions and may generally be extracted from basic aqueous solutions into an organic solvent. 'Neutral drugs' are generally unaffected by changes in pH and they will usually stay in whichever phase they are more soluble.

An example of such an extraction is the separation of a mixture of codeine, butalbital, and acetaminophen. [Figure 3](#) is a flow diagram illustrating this extraction. Butalbital is an acidic drug, whereas codeine and acetaminophen are basic drugs. The drug mixture is added to some acidic water, mixed, and dichloromethane is added. The butalbital will partition into the organic phase, which can then be drawn off and evaporated to recover the drug. The codeine and acetaminophen remain in the aqueous phase, which is then made basic with the addition of a strong base, such as NaOH. Additional dichloromethane is then added. Although acetaminophen is a basic drug, it is mostly insoluble in dichloromethane; therefore, most will remain in the aqueous phase. The organic phase containing the codeine and a small amount of acetaminophen are drawn off and additional basic water is added. The remaining acetaminophen is partitioned into the aqueous phase in which it is more soluble, and the organic phase can then be drawn off and evaporated to recover the codeine.

Solvent extraction is used in the analysis of fiber dyes not only to extract a dye from an evidential fiber, but also to classify the dye. A comprehensive approach to fiber dye extraction has been developed by the Forensic Science Service in the United Kingdom; an example of this approach is shown in [Figure 4](#). The reader is directed to the Further Reading for details.

Solid-Phase Extraction

In some situations, liquid-phase extraction may not be suitable. For example, a separation may not be possible if the

compounds to be separated are very similar in polarity, or exhibit similar acid/base properties. There also may be issues when sample amount is limited or there are significant matrix issues, for example, biological samples such as blood and urine. In these situations, solid-phase extraction, which relies upon adsorption of components on a solid phase can be used. The adsorbed analytes can be preferentially removed by use of a suitable solvent (Figure 5). This approach, which strictly is a miniaturized form of liquid–solid chromatography, is widely used in analytical chemistry to ‘clean up’ dirty samples and preconcentrate target analytes for subsequent measurement.

A wide range of different adsorbent chemistries are available in prepackaged polymer or glass cartridges. SPME (described above) is a recent variation on this theme.

Purification via Chemical Reaction

Purification can also be achieved by salt formation or chemical derivatization. Both techniques involve addition of a chemical to react with the target component to form a complex, which has properties allowing it to be separated from the rest of the mixture. An example of this is the separation of inorganic acids

Figure 5 Separation of dye mixture by solid-phase extraction. Each elution used a different solvent. (Waters).

from a solution. These types of liquids are often encountered in poisoning cases (e.g., a suspect puts an acidic solution in a victim's drink) or in clandestine laboratories where acids are utilized in the production of illicit drugs. Knowing that an acid plus a base yields a salt plus water, concentrated ammonium hydroxide is added to the acidic solution, which forms an ammonium salt with the acid. As these salts are insoluble in acetone, addition of this solvent precipitates the ammonium salt from solution. Infrared analysis of the ammonium salt allows the analyst to determine the composition of the acid originally in solution. Production of ammonium chloride indicates that hydrochloric acid was present, and ammonium sulfate indicates that sulfuric acid was present.

There are hundreds of chemicals used to derivatize compounds with the added benefit that the complex formed by derivatization is generally more stable than the underivatized compound. An example of this additional stability is the silylation of psilocybin with BSTFA (*N*, *O*-bis-(trimethylsilyl)-trifluoroacetamide). Psilocybin (the active drug present in psilocybin mushrooms) undergoes thermal decomposition on heating due to the loss of the dihydrogen phosphate ester group; therefore, due to the heat of the injector, gas chromatography-mass spectrometric (GC-MS) analysis produces chromatograms and spectra that are identical with psilocin. Silylation of the psilocybin before GC-MS analysis 'locks in' the phosphate group, eliminating its thermal instability on injection.

Separation of Enantiomers

Enantiomers (isomers that are mirror images of each other) are traditionally difficult to separate. Enantiomers have identical melting points, boiling points, density, dissociation strengths, reaction rates, and solubilities. The only variable in which they can be distinguished is the direction of their refraction of

plane-polarized light (optical activity). Products formed by the reaction of enantiomers with optically inactive reagents are identical, as are the rates of reaction. The reaction rate of enantiomers with reagents that are themselves optically active is not identical and may be so different that one isomer does not react at all. Derivatization of enantiomers with optically active reagents may lead to their separation and their isomeric determination. This is usually accomplished by a chromatographic method following derivatization. Reaction with an optically inactive derivatizing reagent may also yield information about the optical activity of a compound, albeit indirectly. An example of this is in the determination of the optical isomer of methamphetamine. Under US Federal sentencing guidelines, *D*-methamphetamine (+ rotation) and *D*, *L*-methamphetamine (racemic) carry tenfold the penalty as *L*-methamphetamine (– rotation), necessitating the determination of the optical isomer. The methamphetamine can be derivatized with phenylisothiocyanate (PIT). The resultant derivative precipitates with the racemic mixture but not with the single enantiomers; therefore, if the reaction results in precipitation of the derivative, a racemic derivative of *D*, *L*-methamphetamine–PIT forms and its chemical structure is confirmed via infrared spectrometry. If no precipitation occurs, standard *L*-methamphetamine can be added to the PIT-sample complex and if precipitation occurs after the addition, it can be concluded that *D*-methamphetamine was initially present. If no precipitation occurs, the entire process must be repeated with the addition of standard *D*-methamphetamine instead of *L*-methamphetamine. If precipitation occurs upon the addition of *D*-methamphetamine to the PIT-sample complex, it can be concluded that *L*-methamphetamine was initially present.

Microcrystalline Tests

Although superseded in many disciplines by instrumental methods, microcrystalline tests are an excellent example of

the use of chemical reactions for the separation and identification of some compounds. Typically microcrystalline tests are performed by mixing a small drop containing the substance to be tested with a small drop of reagent. After a few seconds to minutes, characteristic crystals of the resulting compound can be observed and identified via polarized light microscopy.

Ion Mobility Spectrometry

Instruments, such as the Barringer Ionscan, have become increasingly popular due to their portability, sensitivity, and speed of analysis. Ion mobility spectrometry (IMS) has been used as a forensic screening technique in the areas of drug and explosive residue. In this technique, samples are swabbed with a filter paper and inserted into a heated sampling device, which serves to ionize the sample. The ions are released into a separation region that is under the influence of an electric field. The ions move through this region at a rate proportional to their mass and against the flow of a gas. Negatively charged ions move quickly through the field toward the cathode and their time of flight recorded. This time of flight can be compared to the time of flight of a variety of substances across the field allowing tentative identification of the substance. These instruments are commonly used in airports to rapidly screen luggage for explosives and drugs. In the last few years, they have been increasingly used at the scenes of clandestine laboratory and bombing investigations and prison inspections.

Glossary

Chemiluminescence The emission of radiation (light) by a sample, after the sample undergoes a chemical reaction.

Fluorescence The emission of radiation (light) by a sample, after the sample absorbs radiation (light), usually of a different wavelength.

Spectrometer An instrument designed to measure the amount and wavelength distribution of light either absorbed or emitted by a sample.

Spectroscopy A set of techniques which measure the amount and wavelength distribution of light either absorbed or emitted by a sample.

Synchrotron A large device (usually 100–200 m in diameter) that produces extremely intense light by accelerating electrons close to the speed of light, around an almost circular track.

Nomenclature

AAS	Atomic absorption spectroscopy
AES	Atomic emission spectroscopy
cm^{-1}	Unit used to measure the number of wavelengths per centimeter
DRIFTS	Diffuse reflectance infrared Fourier transform spectroscopy
IR	Infrared

IRS	Internal reflectance spectroscopy
NMR	Nuclear magnetic resonance
SEM-EDX	Scanning electron microscopy–energy-dispersive x-ray
SEM-WDS	Scanning electron microscopy–wavelength-dispersive spectroscopy
UV-vis	Ultraviolet–visible
XRF	x-Ray fluorescence

Introduction

Spectroscopic techniques are widely used in forensic laboratories for quantitative and qualitative analysis. The techniques described in this article are those that are most commonly encountered in forensic laboratories. Generally, these can be classified as being used for either identification or measurement of substances or elements, although some techniques can be used for both.

Identification of Substances

Infrared Spectroscopy

Infrared (IR) spectroscopy is unsurpassed as a universal technique for the identification of the class of compounds present within a specimen. For example, it is very easy to identify fibers on a generic basis such as acrylics, nylons, and polyesters, or paints on a generic basis such as alkyds, acrylics, urethanes, and nitrocellulose. With the advent of computerized spectral databases and chemometrics, it is now possible to extend the technique to allow subgeneric discrimination. Unique identification of a particular substance is possible if the sample is not a mixture. However, as similar substances within a particular class have similar functional groups, it is often difficult to discriminate between substances within a class, particularly if mixtures of members of the class are present. **Figure 1** gives the

spectral data for three common phthalate ester plasticizers. Another example of the limitation of the technique is differentiation of paints within the alkyd class.

IR spectroscopy can be used to elicit structural information that might be difficult or impossible to arrive at using other techniques. One area of great utility is the characterization of chemical isomers. For example, the diastereoisomers

Figure 1 Infrared spectral data from three phthalate ester plasticizers: (a) dimethyl phthalate; (b) diisooctylphthalate; and (c) dihexylphthalate.

ephedrine and pseudoephedrine are difficult to distinguish by mass spectrometry, and depending on the stationary phase used, might exhibit identical retentions in a gas chromatograph. As absorption wave numbers depend on molecular geometry, IR spectroscopy can distinguish between diastereoisomers (e.g., ephedrine and pseudoephedrine), positional isomers of aromatic substances (e.g., the various isomers of dimethoxyamphetamine, or trimethyl benzene), other stereoisomers (e.g., cocaine, allococaine, pseudococaine, and pseudoallococaine), and isomeric functional groups (e.g., butyl nitrite, isobutyl nitrite, and sec-butyl nitrite). Subtle chemical changes can result in significant changes in the IR absorption. For example, the N–H stretch in amine salts of drugs is found between 2500 and 3000 cm^{-1} , while the N–H stretch in their free bases is found well above 3000 cm^{-1} .

IR spectroscopy can provide information relating to the total composition of the specimen, unlike chromatographic techniques, which usually require an extraction step and have restrictions due to volatility and solubility. Such techniques therefore can only provide partial information as to the specimen. In the examination of paint, for example, IR spectroscopy can provide information as to the polymeric binder as well as the inorganic extenders and pigments. **Figure 2** shows the spectrum of a paint specimen, and spectra for kaolin and silica. Spectral features due to those minerals as well as the polymer are evident in the spectrum of the paint. Inorganic halides are virtually transparent to IR radiation; therefore, the presence of, for example, common salt or potassium bromide in a specimen cannot be deduced. Metals and some of their oxides also do not give useful data.

However, while quantitative measurements are possible using IR spectroscopy, they are difficult. First, the limit of detection of a substance in the presence of another is about 5%. IR spectroscopy is therefore not a good technique for the detection or identification of trace copolymers, residual solvents, low-level pigments, some additives in polymer samples (e.g., fibers or paints), manufacturing impurities, or trace contaminants in illicit drugs. Second, the matrix contribution must

Figure 2 Infrared spectroscopy of paint films allows identification of inorganic compounds as well as the polymeric binder. In this example, neither the binder nor the inorganic substances dominate the spectrum. (a) Paint film; (b) infrared spectrum for silica; and (c) infrared spectrum for kaolin.

be accounted for in quantitative IR spectroscopy. Hence, the matrix must be well characterized. For example, relatively accurate quantitative analysis of unknown mixtures of heroin in sucrose can be performed by using a set of calibration data comprising various known mixtures of heroin in sucrose, and if no other substances are present in the mixture, but the level of heroin in glucose cannot be determined using heroin–sucrose calibration data.

The presence of different substances in a mixture can mask or disguise the absorption of other components. **Figure 3** shows the spectrum obtained from a sample of colored matter (apparently electrical wire insulation) taken from a pair of wire cutters suspected of being used to disable a burglar alarm. Spectral features due to the polymer (polyvinyl chloride) are almost nonexistent; the majority of peaks are due to plasticizer (a phthalate ester, or a mixture of them) and calcite. As a means of comparison between the recovered chips of plastic and insulation taken from wire in the burglar alarm, IR spectroscopy is particularly poor. Spectral features, due to the important polymer component, are masked by peaks due to additives.

IR spectroscopy can be carried out on microscopic specimens (down to about 10 μm^2) using an IR microscope. This instrument is simply a device which condenses the IR beam from its standard size (usually about 10 mm) to much smaller dimensions (about 0.18 mm). This task is accomplished with a microscope, which is also used to allow high-magnification viewing of the specimen and accurate positioning of it in the beam. The technique is referred to as IR microscopy or, more accurately, IR microspectroscopy.

IR microspectroscopy is the usual technique employed in the analysis of small samples of paint (e.g., motor vehicle accidents, breaking, and entering), single textile fibers (evidence of contact), particulate material (explosive residues such as ammonium nitrate, smokeless powder, etc.), and concentrated extracts of low-dosage drugs (e.g., an extract from a lysergic acid diethylamide (LSD) dose evaporated to a microscopic spot). It is possible to record spectra from a few nanograms of material using an IR microscope.

In practice, IR microspectroscopy differs a little from IR spectroscopy. Sample preparation is a little more tedious, as manipulations must be carried out with the aid of a microscope. In most instances, steps must be taken to reduce the

Figure 3 Infrared spectrum recorded from a small piece of plastic electrical insulation. Peaks indicated are due to plasticizer or calcite. In this spectrum, the inorganic fillers dominate; therefore, the polymeric substance (polyvinylchloride) is very difficult to identify.

thickness of the specimen to about 10–30 μm , otherwise bad artifacts will be evident in the spectrum. As with any other spectroscopic technique, the homogeneity of the specimen is an important issue. For example, in some paint samples, the granule size of some inorganic fillers can be relatively large: on the microscopic scale, some samples are quite heterogeneous. Even though it is possible to see very small objects ($<10\ \mu\text{m}$) with the IR microscope, diffraction of the IR beam inhibits the acquisition of high-quality spectra. A description of diffraction and its effects on microspectroscopy is beyond the scope of this text; the reader is referred to the bibliography for useful references.

Much of the above has described the measurement of absorbed IR radiation being transmitted or passing through a specimen. There are two other techniques in widespread use in forensic laboratories; in both internal reflectance spectroscopy (IRS, sometimes referred to as attenuated total reflectance spectroscopy) and diffuse reflectance spectroscopy, the IR radiation interacts with the surface of a sample instead of passing through the sample.

In IRS, the IR beam is caused to reflect inside a special crystal, which is in contact with the sample. Some components of the IR electromagnetic radiation extend beyond the crystal and interact with the surface of the sample to a depth of about 1 μm . The absorption of the IR radiation by the specimen is recorded as the IRS spectrum. The physics of IRS means that absorption of longer wavelengths (smaller wave numbers) is enhanced compared to the absorption of shorter wavelengths.

In diffuse reflectance spectroscopy, the IR beam is directed onto a finely powdered sample. The IR beam is reflected from both the surface layer and from particles below the immediate surface. In a manner similar to other IR techniques, the absorption of IR radiation by the sample is recorded as the diffuse reflectance spectrum. Note that the acronym DRIFTS (diffuse reflectance IR Fourier transform spectroscopy) is sometimes used, where the Fourier transform refers to the type of spectrometer used to collect the IR spectrum.

Raman Spectroscopy

Raman spectra look like, and give similar information to, IR spectra. As Raman signals arise from a simultaneous absorption/emission event, while IR signals arise from absorption only, some peaks will present in only either IR or Raman spectra, while most peaks will present in both.

Raman spectroscopy can be done with any single-wavelength incident beam, which is higher in energy than the IR absorption, but in practice, visible laser sources are often used. Fluorescence from the specimen (e.g., ink) or from the background matrix (e.g., paper) can make it difficult to detect the Raman signals, but this is usually overcome by use of a different light of slightly longer wavelength.

There are several advantages of Raman spectroscopy. First, the single-wavelength incident beam permits the use of laser light sources, whereas the sources in IR spectroscopy must cover all IR wavelengths, requiring the use of less intense light sources. Second, the minimum beam diameter and spatial resolution is related to the wavelength, which means that a Raman source can be focused to about 1 μm , significantly smaller than for IR. This has special advantages for Raman

microspectroscopy. This means that if two different substances are present side by side, such as adjacent layers of paint or the two components of a bicomponent fiber, it is much easier to achieve a spectrum of one of the substances free of spectral interference from the other. Third, as Raman spectroscopy is not a transmission technique, there is no requirement to make the specimen thin enough to transmit radiation, as is the case in IR microspectroscopy; therefore, specimen preparation is very simple. Fourth, specimens can easily be analyzed as solutions in water or as films on a glass microscope slide, as these media do not absorb the visible Raman beam; this is not possible for IR spectroscopy. Finally, developments in confocal Raman microspectroscopy will allow accurate control over the probe beam so it can be brought into focus in a very small volume within the specimen, not just on its surface. This will allow evaluation of the entire specimen, and might be a useful way of avoiding excess fluorescence arising from surface contamination, textile brighteners, etc.

x-Ray Fluorescence and Scanning Electron Microscopy Energy-Dispersive x-Ray

x-Ray fluorescence (XRF) is primarily a method for identifying the elemental composition of a sample. The way in which the atoms are combined or bonded to other atoms in the sample does affect the energies of the XRF, but this subtle change in energy is difficult to use for identification, unless there is additional information from other analyses. Therefore, XRF is used to determine the chemical elements present in the specimen, but not the chemical speciation or functional group of those elements. For example, XRF can be used to identify particles containing chlorine arising from chlorate-, perchlorate-, or hypochlorite-containing improvised explosive devices, but XRF is not used to distinguish these oxyanions from each other, or from chloride, which is not characteristic of explosive residues. Similarly, in cases of black powder explosions, XRF can be used to identify the presence of potassium and sulfur, but not to prove whether the sulfur is present as one of its oxyanions, or as elemental sulfur, or sulfide.

MicroXRF is a version of XRF that is used for the analysis of microscopic specimens. A light guide is used to 'focus' x-rays in a spot about 10 μm in diameter. The specimen is viewed under low magnification with the aid of a video camera, which allows control over the area illuminated by the x-ray beam and therefore the region in the specimen that is analyzed.

x-Rays will penetrate a long way into the specimen and interact with a relatively large volume of the specimen. Therefore, with thin, microscopic specimens, such as small flakes of glass or thin pieces of paint, most of the x-ray beam will pass right through and fluorescence will be minimal. Hence, XRF is most useful for the elemental analysis of relatively large, easy-to-find specimens such as thickly layered paints, big chips of glass, fibers, and pieces of automotive accessories.

Emission of x-rays can also be achieved by irradiating the specimen with an electron beam, which causes similar electronic excitation and subsequent x-ray emission. The spectral information is the same as from XRF, but this process is not called fluorescence because the initial excitation is not from the absorption of electromagnetic radiation. In scanning electron microscopy (SEM), as an electron beam is moved over the

specimen, back-scattered electrons and secondary electrons, which are emitted from the specimen, are detected. The correlation between the number of detected electrons and the position of the electron beam builds up a point-by-point picture of the specimen. The electron beam also causes x-ray emission. The correlation between the x-ray wavelength and intensity and the position of the electron beam builds up an elemental map of the specimen. As the electron beam does not penetrate the sample to any great extent, this spectroscopic technique examines the chemical elements present in the surface of the specimen. The emitted x-rays can be analyzed by passing the x-rays through a special crystal that acts like a prism and disperses the radiation in space. This technique is referred to as wavelength-dispersive spectroscopy (WDS). Alternatively, the x-rays can be analyzed on the basis of their energy: this approach is called energy-dispersive x-ray (EDX) microanalysis, or energy-dispersive spectroscopy (EDS). While wavelength-dispersive spectrometers have superior performance, EDX spectrometers are more commonly used in forensic laboratories because of their lower cost.

In SEM-WDS and SEM-EDX, the electron microscope can achieve a wide range of magnifications simply by causing the electron beam to impinge on either a very small area (high magnification, with less than 1 μm diameter) or relatively large area (low magnification) of the specimen. SEM-WDS and SEM-EDX give higher spatial resolution than XRF, and without the problems of x-ray emission from underlying layers or the mounting substrate. For large homogeneous samples, inductively coupled plasma or atomic absorption techniques, or even XRF, have significantly lower limits of detection than SEM-WDS and SEM-EDX. However, for specimens that are heterogeneous on microscopic scales, SEM-WDS and SEM-EDX are far superior to the other techniques.

For example, one common application of SEM-EDX is in the detection and analysis of gunshot residue (GSR) particles. Most GSR particles are characterized by their spherical shape and the presence of lead, barium, and antimony. If atomic absorption spectroscopy (AAS) or XRF was used to find lead, barium, and antimony in a sample, interpretation would be difficult, because these other techniques would be unable to distinguish between true GSR and microscopic heterogeneous mixtures of pure lead particles, pure antimony particles, and pure barium particles, a situation which does not point to the presence of GSR particles.

Both XRF and the hyphenated SEM x-ray techniques work best for heavy elements, which have large numbers of electrons in each atom. With appropriate signal processing, the SEM image can be tuned to show only elements of high atomic mass such as lead, while light elements remain invisible. Under these circumstances, searching a large matrix for minute amounts of heavy elements, such as those in GSR particles, can be automated, as long as there is enough contrast between the heavy elements and the matrix.

Although SEM-EDX has a few shortcomings, it is a very versatile and efficient technique for elemental analysis. Although it suffers from an apparently high limit of detection, the ability to analyze submicrometer particles or specimen areas compensates to a great extent. If a particle or unusual region in the specimen can be found using the imaging options, then it can be analyzed, giving the technique an extremely low working limit of detection. Furthermore, the

instrument allows imaging of specimens at high or low magnification with very high depth of focus. This facility can provide useful morphological information relating to trace evidence, such as fiber cross section and surface morphology. Finally, an important consideration is that often the specimen needs little or no treatment before analysis.

Nuclear Magnetic Resonance Spectroscopy

In a forensic context, nuclear magnetic resonance (NMR) spectroscopy finds its greatest application in the analysis of organic compounds. However, the impact and use of NMR in the forensic context has been limited by the high purchase cost of NMR spectrometers, the operating cost of liquid helium and liquid nitrogen to maintain the cold temperature of the superconducting magnets, the limitation that analytical mixtures must be relatively simple as commercial instruments with interfaces to chromatographic techniques are not available, and the relatively high limits of detection.

The main use of NMR in the forensic context is to analyze and characterize illicit drugs (especially new designer drugs) and unusual precursors or intermediates in clandestine laboratories. NMR is normally operated in one of two modes, proton mode, which detects signals from the nuclei of hydrogen atoms, and carbon-13 mode, which detects signals from ^{13}C nuclei. In carbon-13 mode, it is usual to see a signal for every nonequivalent carbon atom within the specimen. Therefore, if the specimen is a pure sample heroin, for example, 21 distinct signals at characteristic frequencies are observed. This is an extremely high level of discrimination. In proton mode, the situation is analogous.

The ability of NMR to provide enormous structural detail becomes a limitation in the case of complex mixtures, because it is difficult to determine which signals are associated with which component in the mixture. Furthermore, NMR is often not able to resolve large numbers of overlapping signals, especially those that arise from very similar environments, such as the spectra of polymers and oligomers. Therefore, NMR is not useful in the forensic discrimination of paints or fibers, or in trace analysis, for example, detection of explosives in bombing debris, or drugs in body fluid.

One of the greatest benefits of NMR spectroscopy is the predictive structural information that can, with skill, be elucidated from the spectrum of an unknown substance. The number of distinct carbon and hydrogen atoms within the unknown molecule can be deduced from the carbon-13 and proton spectra. Furthermore, the proton NMR spectrum gives information about which protons are neighbors to other protons. The presence of heteroatoms and carbon-carbon multiple bonds can be inferred by careful examination of the position of each peak in the carbon-13 and proton spectra. Finally, more sophisticated NMR spectra, using complicated sequences of radio pulses, can be used to determine not only the connectivity of the moieties, but also the three-dimensional arrangement of parts of the unknown substance.

Specimen preparation is very simple; the substance can be dissolved in a suitable solvent (heavy water, deuteriochloroform, and deuterated methanol) or basic drugs can be extracted from alkaline aqueous solution using a suitable solvent (deuteriochloroform and carbon tetrachloride). If the instrument is

calibrated and an internal standard is included in the protocol, then the test can be quantitative as well as qualitative. The extremely high level of discrimination gives the test a very high probative value. If required, NMR can be used to probe other nuclei, such as ^{31}P or ^{13}C , though the low natural abundance of some isotopes makes the collection of those spectra very difficult and time-consuming. Finally, as the sample can be recovered from the solvent, NMR is also a nondestructive technique.

Quantification of Substances

Spectroscopic methods can be used to measure the quantities of a substance present in a sample. The Beer–Lambert law (or the Beer–Lambert–Bouguer Law) states that the absorbance of radiation at a particular wavelength is proportional to both the distance the radiation travels through a specimen and the concentration of the species that absorbs the radiation:

$$A = \epsilon cl$$

where A is the absorbance; ϵ is the extinction coefficient; c is the concentration of the absorbing species, and l is the path length of radiation through the specimen. The constant of proportionality, ϵ , in Beer's law is called the extinction coefficient. It is a measure of how well a compound absorbs radiation at a given wavelength; it is as characteristic of that compound as other physical constants such as melting point, boiling point, or molecular weight. The chemical literature abounds with extinction coefficients for many substances, including pure drugs and their salts in a variety of solvents at a variety of wavelengths, mostly in the ultraviolet (UV) and visible regions of the electromagnetic spectrum.

Ultraviolet and Visible Spectroscopy

Visible (vis) spectroscopy and UV spectroscopy are usually referred to as a single technique (UV–vis) because the absorption or emission of UV and/or visible light are associated with the same physical and chemical processes in both of these adjacent regions of the electromagnetic spectrum. As many compounds absorb UV and/or visible light, UV–vis is widely applicable to the determination of a wide range of substances. Most of these, especially liquid- and solid-phase samples, have broad peaks and features in their UV and visible spectra that are difficult to use for qualitative identification. However, UV–vis is very widely used in analytical chemistry for quantitative analysis, either as a stand-alone technique or as the most common mode of detection in liquid chromatography and capillary electrophoresis (Figure 4).

A common use for UV–vis spectroscopy in the forensic laboratory as a stand-alone technique is screening powders for the presence of illicit drugs. In this application, UV–vis is quite successful because the technique has a very low limit of detection, powders are usually simple mixtures, and illicit drugs give good signals. Many useful solvents such as water, methanol, ethanol, and acetonitrile are virtually transparent throughout the visible and UV spectrum. It is therefore very easy to prepare a solution of the illicit preparation to an accurate concentration in a solvent that does not interfere with the absorption spectrum. Using the Beer–Lambert Law, the

Figure 4 Ultraviolet absorbance spectra obtained from exemplars of three different classes of automotive clear coat. The differences between Class 1 (2000 Toyota MR-2), Class 2 (2002 Honda Civic), and Class 3 (1995 Chevy Sebring 434) were characterized using principal component analysis. Reproduced from Liszewski EA, Lewis SW, Siegel JA, and Goodpaster JV (2010) Characterization of automotive paint clear coats by ultraviolet absorption microspectrophotometry with subsequent chemometric analysis. *Applied Spectroscopy* 64: 1122–1125, with permission from Society for Applied Spectroscopy.

absorbance of the specimen, the optical path length (usually 1 cm in standard sample cells), and the extinction coefficient of the drug, the concentration of drug present in the solution of the illicit preparation can be determined. In practice, it is more common to compare the absorbance of the specimen against standard solutions of known concentration, rather than relying on the literature extinction coefficients, because the standards can be prepared to include impurities which are present in the specimen, and which may change the effective extinction coefficient. The attraction of such an analytical strategy is that it is very inexpensive, rapid, and simple. Furthermore, if the UV–vis spectrometer has been properly calibrated using absorbance and wavelength references, a pure reference drug standard may be not absolutely necessary in order to quantify the drug because extinction coefficients are universal constants.

This facility for accurate, standardless quantification is unique to UV–vis spectroscopy; separation techniques (e.g., gas chromatography, liquid chromatography, capillary electrophoresis) require a reference substance in order to calibrate the response with respect to amount, and for other spectroscopic techniques (e.g., IR spectroscopy), extinction coefficients are not available. UV–vis spectroscopy is not generally applied to the quantitative assay of illicit drug preparations, however, because the technique in general has severe limitations for the analysis of uncharacterized mixtures. However, when a mixture is well characterized and there is some degree of separation between the spectral peaks arising from the compounds in the mixture, UV–vis spectroscopy can be useful.

Another example is the estimation of carboxyhemoglobin in human blood. The spectral characteristics (i.e., absorption maxima and extinction coefficients) for carboxyhemoglobin and interfering blood pigments (e.g., oxyhemoglobin and methemoglobin) are well known. For a blood specimen of unknown carboxyhemoglobin saturation, it is a simple matter to deconvolute mathematically the spectral contributions of interfering blood pigments from the bands due to carboxyhemoglobin.

Figure 5 Visible microspectra of two different, metameric turquoise wool fibers. Although these fibers are of an identical color to the human eye, they are easily distinguished using visible microspectroscopy.

A major application of visible spectroscopy is the objective color comparison of evidential material such as fibers or paint. The human eye and brain interpret the visible spectrum of light reflected from an object as its color. However, the human eye is a low-resolution transducer, and it can be fooled into interpreting two closely related colors as identical. **Figure 5** shows visible spectra acquired from two different turquoise wool fibers. Even though the spectra from the two fibers are noticeably different, the eye perceives the two fibers to be identical in color. In the modern forensic laboratory, therefore, visible spectroscopy is invaluable as a means of confirming whether two objects are of the same color, or refuting the observation.

Conventional UV–vis spectrometers cannot acquire spectral data from microscopic samples of paint, or from short pieces of single textile fibers. The instrument used is referred to as a visible microspectrometer, and it functions in the same way as the IR microscope described earlier. Unlike the IR microscope, visible microspectrometers allow analysis and visualization of objects less than 10 μm in size. This is possible because visible light suffers less diffraction than IR radiation. Visible spectroscopy should be considered a color analysis technique, not a pigment analysis technique. This is because visible spectroscopy is not always capable of resolving different compounds (or different blends of compounds) that have the same color. Reliable pigment analysis is achieved only when visible spectroscopy is used in conjunction with other techniques. For example, thin-layer chromatography (TLC) could be attempted on pigments extracted from fibers, or SEM–EDX microanalysis could be used to characterize pigments in paint.

Pigments absorb radiation in the UV region as well as in the visible region, and paints designed for outdoor application can contain compounds that are active in the UV. Therefore, compared to visible spectroscopy, UV–vis spectroscopy can be expected to offer enhanced discrimination. However, the standard optics present in visible microspectrometers are usually made of glass, and these strongly attenuate UV radiation. It is possible to purchase microspectrometers equipped with quartz optics, which allow the spectrometer to cover the UV and visible range. When faced with the high cost of quartz optics, however, forensic laboratories tend to rely on visible

microspectroscopy and enhance pigment discrimination with a simple, inexpensive technique such as TLC.

AAS and Atomic Emission Spectroscopy

AAS and atomic emission spectroscopy (AES) are normally used to quantify metallic elements present in a specimen. A specimen is dissolved in a suitable solvent. Chemical treatment may also be required if the sample is not soluble. Depending on the exact instrumentation, the solution is aspirated into a flame or plasma torch, which converts the analytes into gaseous atoms. Atomic absorption spectrometers use lamps that are specific to the measurement of a single metallic element, or multi-element lamps that are specific to a small number of metallic elements.

Using the Beer–Lambert law, the absorbance of light by the sample at a wavelength that is specific to that metal gives a measure of the amount of that metal present in the sample. Note that this method gives a measure of the total amount of a specific metal that is present, and that there is no information about the original speciation of that metallic element. AES is similar to AAS in many regards, except that the emission of the heated gaseous metallic atoms is measured.

The primary advantages of AAS and AES for the forensic scientist are unsurpassed limits of detection, accuracy, and precision for elemental analysis. However, AAS and AES are not necessarily the most effective means by which a forensic scientist can conduct elemental analysis. First, atomic spectroscopy is destructive; the sample presented for analysis is usually treated with a very strong acid to form a solution, and then irreversibly aspirated into the instrument. Second, because the sample is homogenized by dissolution, atomic spectroscopy cannot yield any information as to spatial distribution, or compounds present in the specimen. For example, a sample might be found to contain Fe and Cr. Although this suggests that the sample contains a chromium–steel alloy, one cannot rule out the possibility that iron chromate and iron dichromate are present, or that the sample might contain granules of iron, chromium, iron oxides, etc. Third, any contaminant associated with the specimen will be digested along with it, and will contribute to the results. Fourth, although atomic spectroscopic techniques do have very low limits of detection, they are often not low enough to detect trace elements in trace evidence. This is because the specimen must be made into a solution of relatively large volume (usually 0.5–5 mL). As a consequence, trace elements in, for example, small chips of glass or paint yield very dilute solutions. Finally, some techniques, such as flame AAS, only allow sequential analysis of target elements; one analytical test provides data with respect to only one element. As it is not possible to screen a specimen for many elements in one test, the analysis is not particularly efficient, especially with regard to specimen consumption.

Paradoxically, given the very low limits of detection for these techniques, they are of greatest use in the analysis of relatively large specimens, and given that the technique is destructive, specimens must be big enough to allow subsampling. Such specimens could be human tissue for toxicological analysis, and milligram-size pieces of glass, paint, and metals.

Another strong application of atomic spectroscopy is the analysis of illicit drug powder samples. The low limits of detection that can be achieved allow many trace elements to be detected in heroin, for example. It is possible to identify the source country of the drug on the basis of the suite of elements it contains.

Some of the major shortcomings of atomic spectroscopy can be rectified by the use of a laser ablation source. In this technique, a laser beam is used to vaporize very small quantities of the specimen which are then swept into the instrument, without the need for digestion of the specimen. It is possible to allow the laser beam to dwell on the specimen for some time before analysis, thereby effectively removing any surface contamination. As the laser beam can be focused to a small spot size, it is possible to sample and analyze discrete regions within the specimen. This allows some identification of the spatial distribution of compounds within the specimen. Finally, the laser ablates only a tiny amount of material, leaving the remainder of the specimen intact for further analysis.

Related Techniques

Molecular Fluorescence and Chemiluminescence

Fluorescence has three important applications in forensic science. Perhaps the most widespread use is not in relation to spectroscopy at all, but image or specimen enhancement in the fields of ink comparison, latent fingerprint enhancement, and classification of textile fibers. Another use is in relation to chromatographic detection associated with separation techniques, such as high-performance liquid chromatography and capillary electrophoresis, where extremely low limits of detection can be realized. Finally, molecular fluorescence can be used as a spectroscopic technique (spectrofluorimetry).

Chemiluminescence is a related emission technique, where molecules are elevated to an excited state by a chemical reaction, rather than absorption of light. Chemiluminescence is most commonly used for image or specimen enhancement in the detection of blood at crime scenes, as a quantification method either by itself or in relation to chromatographic detection and is finding increasing use for the rapid screening of illicit drugs. While chemiluminescence is a spectroscopic process, in these forensic applications, it is not used as a spectroscopic technique and will not be discussed further here.

Although spectrofluorimetry is related to UV–vis spectroscopy, there are some significant differences. One distinguishing property of fluorescence, a feature that is both its biggest asset and its biggest drawback, is that not all molecules exhibit this behavior. In general terms, only some inorganic compounds, aromatic compounds, or highly conjugated organic systems are fluorescent, particularly if oxygen or nitrogen atoms are attached. The presence of electron-withdrawing groups (e.g., halogen atoms, nitro groups) diminishes or even completely quenches fluorescence in these substances. On the positive side, therefore, techniques based on fluorescence can have very low limits of detection because spurious background signals are not likely to arise. As the excitation radiation is of a shorter wavelength than the fluorescence, it is possible to enhance detection further by filtering out interference from

the exciting radiation. Spectrofluorimetry has a potential for high discrimination due to the low number of fluorescent compounds. Furthermore, the exact nature of the emission spectrum is linked to the nature of the excitation, and this has a positive effect on discrimination. For example, if two compounds have similar emission spectra, there is the potential for further discrimination if different excitation is required to produce that emission. By means of sophisticated instrumentation (a description of which is beyond the scope of this article), it is possible to scan the excitation radiation in a stepwise or continuous fashion and record emission data.

On the negative side, techniques based on fluorescence will have a very limited applicability because not all compounds fluoresce. As petroleum-based greases, oils, and concentrated fuel residues contain aromatic compounds (in particular, polyheteronuclear aromatic compounds), spectrofluorimetry can be used as a means to characterize them. Some drugs (e.g., LSD, phenothiazine, quinine, and quinidine) are fluorescent, and therefore amenable to qualitative and quantitative analysis using spectrofluorimetry. Some metal atoms can also fluoresce; this finds some application in glass analysis. A major application of fluorescence is through the use of fluorescent labels in DNA sequencing.

Synchrotron Techniques

Synchrotrons are facilities that produce extremely intense light. The actual spectroscopic techniques include IR absorption, XRF, and molecular fluorescence. The much more powerful light sources give significantly better limits of detection, spatial resolution, etc.

In a synchrotron, electrons are accelerated to almost the speed of light, and circulate around an almost circular track. As the electrons change direction of travel from one straight section to another, intense electromagnetic radiation is

Figure 6 Synchrotron radiation x-ray fluorescence spectrum of NIST SRM 612 glass sample. Reproduced from Nakanishi T, Nishiwaki Y, Miyamoto N, et al. (2008) Lower limits of detection of synchrotron radiation high-energy X-ray fluorescence spectrometry and its possibility for the forensic application for discrimination of glass fragments. *Forensic Science International* 175: 227–234, with permission from Elsevier.

emitted. Depending on the spatial arrangement of the magnetic fields used to contain and bend the electrons, emission in particular regions of the electromagnetic spectrum can be optimized. Each emission station or beamline is dedicated to a particular spectroscopic technique.

Limited access to synchrotron facilities means that synchrotron techniques may never become routine in forensic science, but there are many interesting possibilities. Synchrotron XRF has been used for the forensic discrimination of glass samples by analyzing the quantities of Ba, Ce, and Sm at picogram levels and Sr, Zr, Sn, and Hf at 10 pg levels. In another case, synchrotron XRF and x-ray absorption near-edge spectroscopy was used to map the distribution and characterize the form of the arsenic within hair samples; it was possible to distinguish between arsenic which has been ingested and arsenic applied postmortem (**Figure 6**).

Glossary

Spectrometer An instrument designed to measure the amount and wavelength distribution of light either absorbed or emitted by a sample.

Spectroscopy A set of techniques which measure the amount and wavelength distribution of light either absorbed or emitted by a sample.

Introduction

Spectroscopy is the study of electromagnetic radiation and its production from, or its interaction with, matter. Historically, spectroscopy has played an essential role in the development of atomic theory, and it is still extensively used for fundamental studies. Spectroscopic techniques are widely used in forensic laboratories for quantitative and qualitative analysis. This article provides an overview of the basic principles of spectroscopy as applied to analytical measurements; for more in-depth details concerning specific matter–radiation interactions, instrumentation, and techniques, readers are directed to the reference works listed under Further Reading.

Electromagnetic Radiation and Light

Electromagnetic radiation is a traveling disturbance in space that comprises electric and magnetic components. Unlike the field associated with a common magnet or the earth, the magnetic field associated with electromagnetic radiation is constantly changing its direction and strength. The electric field component undergoes exactly the same behavior. **Figure 1** illustrates what would be observed if it was possible to see the electric and magnetic components of a ray of radiation as it passes. It is the interaction of the electric and magnetic components of radiation with matter that are responsible for all the phenomena that are associated with radiation, such as human vision, sunburn, microwave cooking, radio and television, and of course spectroscopy.

There are some important fundamental features of electromagnetic radiation. The periodicity of the disturbance, or the distance between adjacent troughs or adjacent peaks, is referred to as the wavelength of the radiation. The number of times the electromagnetic field undergoes a complete cycle per unit time is called the frequency. The speed with which radiation can travel is limited, and moreover, radiation of all wavelengths travel at a single speed. This is referred to as the speed of light, universally denoted by the symbol c . The speed of light (and every other radiation) is dependent on the substance through which it travels, and reaches a maximum in a vacuum. The speed of light is a constant of proportionality between

frequency and wavelength as described by the following equation:

$$c = \nu\lambda$$

where ν is the radiation frequency, λ is the radiation wavelength, and c is the speed of light.

The interpretation of this equation is that wavelength and frequency are related. Electromagnetic radiation of long wavelength must have a low frequency, whereas radiation of short wavelength must have a high frequency. At the long-wavelength (low-frequency) end of the electromagnetic radiation spectrum are radio waves, while at the other end is high-frequency (short-wavelength) radiation such as gamma rays. Between these extremes lie other forms of radiation, including microwaves, infrared (IR), ultraviolet (UV), and the narrow band of radiation that can be directly observed by humans, visible light.

Radiation carries energy with it, a phenomenon that is made use of in the domestic microwave oven, for example. The radiation is carried in small discrete quantities or ‘quanta’ (singular: ‘quantum’). The amount of energy carried in each quantum is proportional to the frequency of the radiation. As frequency and wavelength have an inversely proportional relationship, the energy quantum carried is inversely proportional to wavelength. Radiation of high frequency and short wavelength (e.g., x-rays, gamma rays), therefore, is of high energy, whereas low-frequency radiation that must have long wavelength (e.g., radio waves) carries little energy.

Matter

Given that radiation is an electromagnetic phenomenon, the main feature of matter as far as its interaction with radiation is concerned is the distribution of its electric and magnetic components.

From the subatomic scale to the molecular, matter exhibits a variety of electric and magnetic features with which radiation can interact. **Figure 2** depicts some of these features for a molecule of ammonia. The forces that hold the molecule together arise from attraction between negatively charged electrons shared between the positively charged nuclei of the nitrogen and hydrogen atoms. The nuclei of each of the hydrogen atoms contain a single charged particle, a proton. The share of

electrons between the hydrogen nuclei and the nitrogen nucleus is not equal; nitrogen commands a larger share. Each nitrogen–hydrogen bond, therefore, has a heterogeneous distribution of charges resulting overall in a positively charged end (toward the hydrogen atom) and a negatively charged end. Such a bond is described as having a dipole moment or being polarized. As each nitrogen–hydrogen bond has a similar polarization, there is an additive effect with the result that the entire molecule is polarized or has a dipole moment.

Each nucleus of the hydrogen atoms comprises a single positively charged proton; each acts like a small rotating bar magnet, or is said to possess magnetic spin. Potentially, the entire ammonia molecule, its bonds, its protons, and its electrons, all have the necessary prerequisites to interact with radiation.

Figure 1 Representation of a ray of electromagnetic radiation traveling through space, left to right. The small vertical arrows represent the strength and direction of the electric field component of the radiation at discrete locations (the magnetic field behaves in an analogous manner). The disturbance is periodic, with the distance between field components of identical strength and direction being the wavelength of the radiation.

Figure 2 Electrical moments in the ammonia molecule. 'A' represents the electrical field resulting from unequal sharing of electrons between nitrogen and hydrogen nuclei. 'B' represents the overall field resulting from combination of three 'A' moments.

Interaction Between Radiation and Matter

In the previous section, it was shown that matter can be thought of as possessing many minute electric and magnetic moments on the sub-atomic and molecular scale. Radiation, which is also electromagnetic in nature, therefore, potentially can interact with matter on this scale. If interaction is to be significant, however, there has to be a match between the frequency of the electromagnetic oscillations executed by the radiation and oscillations of the electromagnetic moments within the matter. The situation is analogous to that of pushing a person on a swing. Say the person on the swing completes a cycle once every second. If the pushes are at some other frequency, then the energy transfer from the pushes is not efficient. The most effective transfer of energy takes place when pushes are in unison with the motion of the swing (i.e., with a frequency of one per second). The interaction between radiation and matter can lead to the occurrence of a variety of phenomena; important ones as far as spectroscopy is concerned are absorption, emission, and scattering.

Absorption

Absorption occurs when electromagnetic radiation is absorbed by atoms, ions, or molecules within a sample. The basis of absorption spectroscopy is the measurement of the manner in which matter absorbs radiation. An appreciation of absorption can be gained by considering the properties of the lens in a pair of sunglasses. Through the lens, the image of the outside world is duller; some of the radiation (light) encountering the lens does not pass through, the lens absorbs it. It leads to an increase in internal energy of the chemical species producing an excited state. This rise in internal energy is related to various transitions in the atom or molecule under investigation, the specific transition being related to the wavelength of electromagnetic radiation being used (see Table 1). These transitions occur at particular wavelengths depending upon the chemical species being studied, this forms the basis of the use of spectroscopy for qualitative purposes. In addition, under particular conditions, the energy absorbed by the chemical species is proportional to the concentration of the absorbing species, allowing quantitative measurements.

Emission

Emission describes the production of electromagnetic radiation by matter as an excited state returns to the ground state. The chemical species may have been raised to the excited state

Table 1 Spectroscopic techniques

Type	Wavelength (m)	Quantum transition
Gamma ray emission	$0.005\text{--}1.4 \times 10^{-10}$	Nuclear
x-Ray absorption, emission fluorescence, or diffraction	$0.1\text{--}100 \times 10^{-10}$	Core electron transitions
Ultraviolet/visible absorption, emission, and fluorescence	$10\text{--}780 \times 10^{-9}$	Valence electron transitions
Infrared absorption and Raman shifts	$0.78\text{--}300 \times 10^{-6}$	Rotation/vibration of molecules
Microwave absorption	$0.75\text{--}3.75 \times 10^{-3}$	Rotation of molecules
Electron spin resonance	3×10^{-2}	Spin of electrons in a magnetic field
Nuclear magnetic resonance	0.6–10	Spin of nuclei in a magnetic field

by absorption of electromagnetic radiation or by a chemical reaction. Since emission is the reverse of absorption, the specific wavelength of electromagnetic radiation observed will depend upon the transition occurring. The basis of emission spectroscopy is the measurement of the manner in which matter emits radiation.

Scatter

Scatter occurs when a small fraction of electromagnetic radiation is scattered at all angles from the original path. Scatter is essentially radiation bouncing off atoms, ions, or molecules.

Instrumentation and Techniques

Spectrometers

Figure 3 depicts the important features of simple instrumentation that can be used for absorption spectroscopy, and a typical spectrum. Although all absorption spectrometers might not be exactly described by Figure 3, as far as this article is concerned,

the important issue is the process leading to the spectroscopic output, and the features of the output itself, rather than the exact mechanism by which it was generated.

Three basic elements are present: a radiation source, a monochromator, and a transducer. It is usual for the source to emit radiation of many frequencies within a region of the entire electromagnetic spectrum, for example, the IR region, the visible light region, x-rays, and so on. The region over which the source operates in a given spectroscopic technique is often used as a means to name that technique. For example, if an IR source is used, the technique is referred to as IR spectroscopy.

The monochromator isolates the wavelength of interest from the source. Ideally it should allow radiation of only one frequency at a time to pass through although, in practice, a band of wavelengths centered around this wavelength is passed through. The radiation is then allowed to impinge on the specimen to be analyzed. The transducer then collects the radiation that is transmitted by the specimen and converts it into an electrical signal, thus allowing measurement of its intensity. Spectroscopic measurement of the specimen is

Figure 3 Schematic diagram of (a) single-beam spectrometer. The spectral output is a plot showing the extent of absorption as a function of the range of frequencies (or wavelength) that strike the specimen (b) dual-beam spectrometer.

performed by ‘sweeping’ the filter through its entire wavelength range allowing (ideally) the detector to measure the radiation transmitted by the specimen one wavelength at a time. A graphical representation of measurements made by the detector is the spectrum of the specimen; typical output is shown in [Figure 3](#).

The horizontal axis in the spectrum defines the range of wavelengths (frequencies) of the radiation that strikes the specimen. The vertical axis indicates how much of each wavelength is absorbed by the specimen (i.e., a peak at a certain wavelength indicates that the specimen absorbs at that wavelength).

Spectrometers can come as single-beam instruments, which have the advantage of simplicity, or as double-beam instruments (see [Figure 3](#)). Double-beam instruments have the advantage of being able to compensate for fluctuations in the radiant output of the source and for variation in source intensity with wavelength. Array spectrometers ([Figure 4](#)) have begun to be widely used for UV–violet visible absorption measurements. They have the advantage of obtaining a complete spectrum at once, which can aid in multianalyte determinations and allow the use of measurement statistics to improve quantitative data.

The ideal of spectroscopy is that because different substances undergo different motions on the subatomic or molecular scale, the spectrum of each must have a unique pattern of peaks. The reality is that substances with very similar structures could behave in a very similar manner, with the result that instrumentation is not capable of discriminating them.

Throughout this article, the term spectrometer has been used to describe the device that acquires a spectrum, whereas spectroscopy has been used to describe the technique. This usage is common in modern publications, but it is by no means the only terminology that might be encountered. The words spectrograph, spectrophotometer, and spectroscope are used to describe apparatus, whereas spectrometry and spectrophotometry are used interchangeably with spectroscopy.

Techniques

As mentioned above, the range of the electromagnetic spectrum that is utilized for particular measurements defines the technique used (see [Table 1](#)). From a forensic point of view,

the following techniques find the widest application for analysis.

Molecular ultraviolet and visible absorbance spectroscopy

Ultraviolet (UV) and visible (vis) absorbance spectroscopy are usually referred to as a single technique (UV–vis), as the absorption of UV and/or visible light is associated with the same physical and chemical processes. UV–vis absorbance involves electronic transitions, and as many compounds absorb UV or visible light, it is widely applicable in chemical analysis. Liquid- and solid-phase samples exhibit broad, featureless, absorbance peaks, and thus, UV–vis absorbance is not generally very useful for identification purposes. However, it is very widely used for quantitative measurements.

Molecular luminescence spectroscopy

As described above, when molecules absorb visible or UV radiation, they are elevated to an excited state of high potential energy. From that state, the molecule can undergo a variety of actions in order to relax. One activity is to emit radiation of lower frequency than that which caused the excitation in the first place. The emitted radiation (fluorescence or phosphorescence) consists of many frequencies of characteristic intensity. Similar to the UV–vis spectrum, the emission spectrum (i.e., the plot of emitted radiation intensity versus wavelength) of a substance can be a means of characterizing that substance. Luminescence has the advantage of improved selectivity, as relatively few compounds exhibit fluorescence or phosphorescence, and sensitivity. It can also be used in imaging, as is commonly done with the detection of latent fingerprints ([Figure 5](#)). Chemical species can also be elevated to an excited state through a chemical reaction leading to the phenomenon of chemiluminescence, best known forensically through the luminol test for bloodstains.

Atomic absorption spectroscopy and atomic emission spectroscopy

Atomic absorption spectroscopy involves absorbance of light by metallic atoms in the gas phase, the light typically being sourced from a lamp specific to the measurement of a single element. Atomic emission is similar but instead measures the emission from heated gaseous metallic atoms. Both of these techniques are widely used for the quantification of metallic elements.

Figure 4 Schematic diagram of an array spectrometer.

Figure 5 Luminescence from latent fingerprints on a paper surface developed with 1,2-indanediol. Excitation using a Polilight PL500 at 505 nm and viewed through a KV550 filter.

Infrared spectroscopy

The atoms of substances are constantly in motion with characteristic vibrational frequencies of 10^{12} – 10^{13} Hz. Most of these vibrations can interact with electromagnetic radiation to absorb in the IR region of the spectrum. Wavenumber or reciprocal wavelength measured in cm^{-1} units are normally used. The absorptions in the mid-IR range, 4000 – 500 cm^{-1} , are commonly used in forensic science.

The exact absorption wavenumber will depend on the bond strength, the relative atomic masses, and the molecular geometry, giving rise to complicated spectra. Particular combinations of atoms, which are bonded together, called chemical functional groups, have distinctive wavenumber patterns. For example, intense narrow peaks near 1700 cm^{-1} are characteristic of a carbonyl group, found in aldehydes, ketones, organic acids, and organic acid derivatives, including proteins and esters. Both IR and Raman spectroscopy are used mainly for the qualitative determination of functional groups.

Raman spectroscopy

In Raman spectroscopy, a sample absorbs the incident beam (usually visible light of a single wavelength) and simultaneously emits radiation of the same or longer wavelength. It is a scattering phenomenon that also changes the wavelength. The Raman shift is the difference in the wavenumbers of the incident and Raman radiation, and are related to the vibrational motions of the atoms in the sample. A small number of molecules in the sample might initially be in an excited state, resulting in the emission of radiation of the shorter wavelength, but the intensity of these emissions is very small. Raman spectra look similar to IR spectra and provide similar information, thus Raman spectroscopy can be considered complementary to IR spectroscopy.

x-Ray fluorescence spectroscopy

In x-ray fluorescence (XRF) spectroscopy, the specimen is irradiated with x-rays, which causes electrons associated with

atoms in the specimen to attain an excited state of potential energy. These excited-state electrons can release that potential energy by emitting energy (fluorescence) in the form of new x-rays. The x-rays are emitted at energies, measured in electron volts (eV), that are characteristic of the atoms present in the specimen. XRF is used mainly for qualitative determination of elements though some quantification is possible.

Nuclear magnetic resonance spectroscopy

In a magnetic field, the nuclei of certain isotopes can absorb or emit radio waves to change their nuclear spin. The exact energies of the spin states depend very markedly on the molecular environment the atoms are in. Nuclei in different environments, therefore, absorb or emit different frequencies within the radio wave region. Measurement of these radio frequencies is the basis of nuclear magnetic resonance (NMR) spectroscopy, with almost all NMR instruments measuring the emission (fluorescence) of radio waves from excited nuclei. There is such a sensitive correlation between the environment and the signal associated with the nuclei that NMR is capable of yielding an enormous amount of information regarding molecular structure, and therefore, unsurpassed specimen discrimination. Furthermore, NMR can be used to analyze a wide range of substances, not limited by molecular mass, volatility, or polarity.

Instruments are categorized by the NMR frequency of protons in the sample. In turn, this frequency depends on the strength of the magnetic field in the instrument, where a stronger magnetic field correlates to great resolving power. Differences in bonding and the molecule near each proton or ^{13}C nucleus cause subtle changes in the NMR frequencies. The changes in frequencies are called chemical shifts and are measured as part per million (ppm) shifts in frequencies relative to a reference frequency, usually the proton or ^{13}C resonance of tetramethylsilane (TMS, $(\text{CH}_3)_4\text{Si}$). The necessity to maintain an unchanging magnetic field and the electronics required to measure shifts in frequency at the ppm level are the reason for the very high cost of NMR instruments.

Field-Deployable Devices

Introduction

The rapid identification of materials encountered at scenes involving hazardous materials, explosives (pre- and postblast), and clandestine laboratories is becoming increasingly important for emergency services and police forensic operations. While there are a number of laboratory-based analytical techniques and instruments that can successfully detect, analyze, and identify the plethora of chemicals that might be encountered at such scenes, the majority of them lack the ability to be truly field deployable. There is, however, an increasing trend toward the miniaturization of laboratory-based technologies that have found application in the needs of field personnel.

In this context, field-deployable devices can be classified as colorimetric presumptive screening tests, handheld devices that can be taken directly into the 'hot zone,' as well as equipment that has been 'ruggedized' and therefore able to be fitted into field-deployable laboratories or deployed into the incident 'cold zone.'

Hazardous Material Identification

Hazardous materials, often termed HAZMAT, are defined as 'anything that, when produced, stored, moved, used or otherwise dealt with without adequate safeguards to prevent it from escaping may cause injury or death or damage to life, property or the environment.' A list outlining the number of chemicals that might be encountered would be in thousands. The task of the emergency services scientific support personnel responding to a scene involving hazardous materials, often termed a HAZMAT incident, is therefore a difficult one. However, by implementing a layered approach in the manner by which field-deployable devices are utilized to assess such scenes allows the scientific personnel to provide a thorough evaluation of the materials involved as well as their effect on the environment. Field-deployable devices that find application in the HAZMAT arena include air monitoring devices (e.g., colorimetric tubes, photoionization devices, and electrochemical monitors), miniaturized infrared (IR) and Raman spectrometers, and field-portable gas chromatograph mass spectrometers.

In addition to traditional HAZMAT incidents, over recent decades, law enforcement and emergency services personnel have developed significant capability in preparing for and

responding to terrorist incidents involving chemical and biological agents and radiological material. Collectively termed CBR incidents, field-deployable devices can be deployed to such incidents for a number of purposes, including

- determining the presence of the chemical/material and identifying contaminated areas,
- stationary warning devices to alert personnel of the presence of a toxic vapor cloud,
- triaging contaminated personnel and monitoring decontamination, and
- identifying material for further confirmatory and forensic analysis.

Explosives Detection and Identification

Explosives detection and identification can be separated into two areas, namely, (1) preblast explosives screening, detection, and identification and (2) postblast explosives residue identification. Members of the traveling public are often exposed to preblast explosives screening at airports, where field-deployable screening devices are employed by security personnel to determine whether a passenger has recently come into contact with explosives and narcotics. Typically based on ion mobility spectrometry, customs officials also utilize such devices to screen passenger luggage at airports. In addition, devices based on IR and Raman spectroscopy can also be utilized for preblast explosives detection and identification. Such devices are often utilized during forensic operations to assist bomb response personnel in assessing the contents of suspicious materials and packages when it is safe for subsamples to be acquired or direct analysis to be performed. Similar devices also find application in postblast explosive residue analysis. However, the analytical requirements for postblast analysis are often more complex, generally involving the analysis of debris that is often contaminated with other material and therefore present in a difficult matrix. In addition, due to the large variety of commercial, military, and homemade explosives that may be encountered, comprehensive identification may often require the application of numerous techniques. In general, field-deployable devices are therefore limited in their application to postblast explosives residue analysis and such comprehensive analysis necessitates the use of laboratory-based equipment and skilled interpretation.

Clandestine Laboratories

Clandestine laboratories most notably involve the synthesis of illicit drugs. Forensic personnel tasked with attending,

assessing, and remediating such scenes are required to first assess the laboratory environment by employing field-deployable devices to determine the composition of the environment (e.g., levels of oxygen, levels of organic vapors that may be explosive) and then to subsequently undertake an evaluation of the chemicals present in the clandestine laboratory, thereby providing some insight into the synthesis being attempted. Colorimetric tests, field-deployable photoionization devices, IR and Raman spectrometers, and portable gas chromatograph mass spectrometers are commonly utilized for such purposes. Clandestine laboratories of a more sinister nature may also be encountered. Such laboratories may include the production of improvised explosive devices, homemade explosives, toxic chemicals, and toxic biological agents. Therefore, clandestine laboratory response personnel require significant training to identify such scenes and also need to be equipped with tools to assist them in their assessment. To this end, field-deployable ion mobility spectrometers, flame photometric detectors, and peroxide-specific fluorescence detectors may be utilized. Importantly, the field-deployable devices employed in more sensitive environments are designed to be intrinsically safe and 'sniff' the area of interest thereby eliminating the need for physical sampling of material, which in the case of sensitive explosive compositions and toxic materials is undesirable. Of course, one limitation of such devices is that they are point-source detectors and reliant on the material of interest to have a sufficient vapor pressure for headspace analysis.

The Challenge of 'In-Field' Monitoring, Detection, and Identification

Most of the miniaturized field-portable instrumentation currently on the market falls into the monitoring and detection categories. Unequivocal identification of agents in the field remains problematic. In the laboratory, scientific personnel have access to a formidable array of floor standing and bench-top instrumentation. For chemical identification, these include instruments based on gas or liquid chromatography and mass spectrometry (MS). The most powerful techniques are when these two techniques are combined. These so-called hyphenated techniques are among the most powerful ways to identify an unknown chemical or confirm the identity of presumptive identification provided by less specific field-deployable devices. Recently, however, there has been a trend to miniaturize and ruggedize these laboratory-based instruments in a form suitable for use in the field. One of the main technological challenges to overcome is to reduce the weight and power requirements.

One of the main issues facing operators of field-deployable devices is the requirement for a strong scientific background. If the instrument manufacturers are to be believed, all one has to do is turn the instrument on, run a sample, and the instrument data system will provide a positive identification. In practice, the same issues facing the laboratory analysis are encountered in the field. Often the results of a library search are not clear, and if the sampling and analysis are not carried out correctly, the results are not valid. In most cases, the skills and experience of a trained scientist adept at interpreting the data provided by

many of the devices described in this paper are essential to correctly interpret the rich information provided by the various techniques.

Principles of Operation of Field-Deployable Devices

As outlined, the monitoring, detection, and identification of chemical compounds of forensic interest in the field remain a challenge. The investigator may be confronted with the task of identifying a particular compound or class of compounds present in a specific sample type, for example, solid, liquid, or vapor/gas. Given the co-occurrence of other compounds that may interfere with the detection of target compounds, resulting in false readings, a discussion of the principles of operation of various detectors and their utility and limitations is warranted.

The discussion broadly classifies detectors under their principle of operation and illustrative uses discussed. However, there is no single detector that can unequivocally identify a particular compound in the field, and verification using an orthogonal detector is necessary to provide confidence in results. To this end, the complementarity between different detectors will be discussed.

Spectroscopic Techniques

Spectroscopy is the study of the interaction of matter with electromagnetic radiation. The behavior of a molecule when a particular wavelength or set of wavelengths is applied causes a subtle change in the electromagnetic absorption and emission of the molecule. Such an interaction can be used to produce a characteristic response of a molecule.

IR Detectors

Principles of the technique

IR detectors are usually employed for the analysis of samples suspected of containing organic compounds. Such detectors emit IR radiation, which causes a change in the rotational/vibrational modes of bonds in a molecule. Bending and stretching of chemical bonds may be induced by a particular frequency of IR radiation. This absorption causes a change in the dipole moment of the molecule corresponding to a specific frequency, thus IR absorption spectra are characteristic of the functional groups present in the molecule. IR spectroscopy generally employs a wavelength range of 400–4000 cm^{-1} .

Strengths and weaknesses

Samples may be introduced to the IR detector in a variety of forms, principal among them are solids and liquids. However, gases may also be monitored by long path length IR spectroscopy. The latter technique has found widespread use in remote monitoring of industrial stacks. Whether solid or liquid, the sample will only induce a response in the IR detector if IR-active components are present. Water, for example, has a strong, broad absorption (OH stretch) of around 3200 cm^{-1}

that may swamp spectral detail of other hydroxyl-containing compounds in the sample. Single-component samples of high purity may result in characteristic spectra. Comparison with libraries provides a further investigative tool for substance identification.

Mixtures may be challenging for field-portable IR units with respect to identification. Recent advances in deconvolution algorithms have provided improved mixture diagnostic capabilities, but the success of this approach lies in the availability of comprehensive IR libraries containing the compound(s) of interest. It cannot be overemphasized that this detector will only respond to the IR-active portion of the mixture. The bulk of the sample may not be IR active, and hence, it would be folly to characterize the sample solely as the IR-active component.

Raman Spectroscopy

Principles of the technique

Raman spectroscopy involves the interaction of monochromatic light, typically supplied by a laser, with the electronic structure of a molecule resulting in light scattering. The molecule is excited to a virtual energy state and on relaxing emits a photon of light and returns to a different rotational or vibrational energy state. The difference in energy level between the ground and new energy state results in the emission of a photon that may be of lesser energy (Stokes shift) or greater energy (anti-Stokes shift). Thus, a change of wavelength from the incident light occurs, resulting in a characteristic spectrum. Raman spectroscopy may be thought of as useful in the analysis of molecules that are easily polarizable, that is, undergo a change in their dipole moment when placed in an electric field associated with incident radiation. The general operating range for Raman spectrometers is $200\text{--}4000\text{ cm}^{-1}$.

Strengths and weaknesses

Raman spectroscopy suffers from a major disadvantage in that only a fraction of the incident radiation is emitted as a Stokes or anti-Stokes shift leading to a lack of sensitivity. Raman is seen as complementary to IR since substances that are IR active may not be Raman active. A classic example is water, which is a strong IR absorber but a weak Raman scattering molecule. Thus, Raman may be used for analysis of aqueous samples, whereas IR becomes saturated above 3000 cm^{-1} due to the OH stretch of water. Also, as glass is a weak Raman-scattering substance, Raman is also routinely used to determine the contents of glass bottles in the field, allowing rapid analysis of suspect samples without opening the container. Solid samples may be analyzed in modern instruments by placing a sample in a glass vial in the path of the laser. In an analogous manner to IR, modern instruments have the ability to identify mixtures using signal processing and libraries.

Raman does suffer from the disadvantage of spectra being swamped by fluorescence if a molecule is excited by the incident laser wavelength. As fluorescence is a more energetically efficient process, the resulting Raman spectra will be useless as a diagnostic tool. Also, some systems require minutes or tens of minutes to acquire a spectrum of sufficient intensity for identification purposes.

Flame Ionization Techniques

Flame Ionization Detection

Principles of the technique

Air sample is drawn into a chamber with a hydrogen/air flame and combusted. The combustion process produces ions and electrons that are detected using an electrode held at a different potential to the combustion jet (commonly $200\text{--}300\text{ V}$). The ions striking the electrode induce a current, which results in a response.

Strengths and weaknesses

The flame ionization detection (FID) is ideally suited to the detection of hydrocarbons in the atmosphere, as nitrogen (main component of air) will not undergo combustion under these conditions and the technique is similarly insensitive to moisture and carbon dioxide. The field-portable detectors are usually rugged and require little maintenance.

Hydrocarbons containing oxygen or sulfur result in a suppressed signal, and therefore, detection limits for such compounds are modest. As the response of an FID is highly nonspecific, a typical air sample, which may contain many hydrocarbon compounds, will produce an FID response. Therefore, the FID may be used to identify the presence of hydrocarbons but cannot identify the compound/compounds.

Flame Photometric Detection

Principles of the technique

Instruments using flame photometric detection (FPD) are designed to specifically detect sulfur (S) and phosphorus (P). Field-portable instruments that can also detect arsenic (As) and nitrogen (N) are now available. The air sample is drawn into the detector and combusted in a hydrogen-rich flame. During the combustion process, the P or S atoms luminesce producing photons of a wavelength specific to each type of atom. P-containing compounds emit at 526 nm , while S-containing compounds emit at 394 nm . Photons of these wavelengths pass through highly selective optical filters to reach a photomultiplier tube (PMT) where the signal is amplified.

Strengths and weaknesses

While the FID is suited to detection of hydrocarbons, the selectivity of the FPD imparted by the hydrogen-rich flame and filters allows P- and S-containing compounds to be detected to parts per billion levels, even in the presence of high hydrocarbon backgrounds. This makes the detector useful in detecting compounds such as traditional nerve agents and organophosphorous pesticides. Generally, P and S can be detected simultaneously, which may be of use if a molecule contains both these atoms, for example, the nerve agent VX.

A response for any FPD channel does not indicate a definitive identification of a compound, but merely that a compound is present in the atmosphere containing P, S, N, As, or a mixture of these. Therefore, the FPD should be used as an indicative technique and in conjunction with other technologies. The FPD is used extensively as a survey technique. Care must be taken to remove the FPD from the source of a positive response and allow it to clear prior to continuing the survey.

This process is usually rapid except when saturation of the detector occurs.

Photoionization Detection

Principles of the Technique

Photoionization detection (PID)-based devices draw air sample into a vacuum cell containing two charged electrodes in which the molecules present are irradiated by ultraviolet (UV) radiation. Ionization of the molecules occurs when the UV energy imparted on the molecule exceeds its ionization energy/potential. Application of potential across the cell containing the ionized molecules leads to an ion current that is measured. PID-based devices can thus determine both the concentration and identity of the molecules present.

Strengths and Weaknesses

PID-based devices exhibit excellent sensitivity and can detect a broad range of chemicals ranging from toxic industrial chemicals to chemical warfare agents. This, however, also unfortunately leads to their poor specificity. Furthermore, although the ionization potential of water exceeds the energy supplied by UV lamps, water vapor in the atmosphere still has a significant effect on PID-based devices.

Ion Mobility Spectroscopy

Principles of the Technique

Ion mobility spectroscopy (IMS)-based devices draw air sample into a reaction chamber where analyte molecules are ionized, most commonly by beta-emitting radioactive sources such as nickel-63. The ionized molecules, formed by ion-molecule reactions between the analyte molecules and ionized reactant ions, are then pulsed into a drift tube that they traverse under the influence of a weak electric field toward an ion collector. In this manner, the ionized molecules are separated and distinguished on the basis of their mass, charge, and mobility.

Strengths and Weaknesses

IMS is a sensitive and rapid analysis technique and its simplicity makes it amenable to miniaturization. IMS-based devices are therefore highly portable and relatively rugged. The technique, however, does exhibit poor selectivity that may cause false alarms due to the presence of interfering analytes. Furthermore, IMS-based devices are prone to oversaturation and contamination and their performance may be affected by environmental conditions such as temperature and humidity.

MS and Gas Chromatography–Mass Spectrometry (GC–MS)

Principles of the Technique

Generally, field-portable MS instruments employ electron impact ionization (EI). In this process, molecules are ionized

using electrons of sufficient energy to fragment the molecule, producing many positively charged ions (cations). The cations are repelled from the source and traverse a mass separator such as a quadrupole or ion trap. Application of voltages and radio-frequencies cause the ions to impact a mass analyzer where their mass is displayed as a plot of abundance versus mass-to-charge ratio. In conventional EI-MS, the resulting mass spectrum is akin to a fingerprint, in that molecules of a particular substance will fragment to give a highly characteristic mass spectrum. This spectrum may be compared to library spectra and a tentative identification can be made.

In-field analysis of samples generally implies that numerous compounds will be present and the diagnostic power of the MS is quickly surpassed. Therefore, a separation technique such as GC is interfaced to the MS, resulting in the hyphenated GC–MS technique. GC–MS provides resolution of complex mixtures into constituent components coupled with the diagnostic capability of MS resulting in a formidable tool for in-field identification. Further discussions will be limited to GC–MS.

Strengths and Weaknesses

GC–MS has the advantage of being applicable to all volatile and semivolatile organic compounds that are not thermally labile. The separation and diagnostic capability of the technique is offset by the analysis time, which may be up to 60 min. The analysis time will depend on the volatility of the compounds in the sample. Various sample introduction methods have been fitted to in-field units, including thermal desorption for air samples, solid-phase micro extraction (SPME) for air and liquid samples, and liquid injection for liquid samples and solvent extracts of solids samples.

GC–MS has the disadvantages of relatively long setup times when transporting to an incident location, ranging from 30 to 60 min, and the requirement of a supply of ultrahigh-pure gas. The long setup time and analysis cycle times are the price paid for a technique that may identify a compound or compounds of interest with a high degree of confidence in field.

Other Detection Technologies

Surface Acoustic Wave Detection

Principles of the technique

Surface acoustic wave (SAW)-based devices consist of a chemically selective polymer-coated piezoelectric crystal onto which target analytes present in the sampled air are reversibly bonded via sorption. The polymer coating is chosen based on varying affinities for a range of organic chemical classes. Once sorption occurs on the polymer present on the piezoelectric crystal surface, a change in the resonant frequency of the crystal occurs and it can be measured. An array of SAW sensors with each sensor coated with selective polymers is normally employed in field-deployable devices, thereby allowing a specific response pattern to be measured and assisting in analyte identification.

Strengths and weaknesses

SAW devices are rapid, sensitive, amenable to miniaturization, and low in cost. However, the sensitivity is also limited to the

sorption ability and capacity of the polymer coating. Furthermore, the relative lack of specificity of the polymer coatings may lead to false alarms. In addition, the performance of the polymer coatings may be significantly degraded in environments with high temperature and humidity, as well as those containing highly reactive vapors. To alleviate these issues, a number of commercial devices are fitted with preconcentrators.

Discussion

The challenges faced by field personnel responding to HAZMAT, clandestine laboratory, and/or explosives incidents and tasked with identifying chemicals of interest include the need for rapid and accurate identification. The plethora of chemicals that may be encountered during such incidents makes this task rather challenging. However, the discussion in this paper has illustrated that numerous laboratory-based analytical technologies, as well as analytical technologies amenable to miniaturization, have been applied to produce commercially available field-deployable detectors and monitors to assist with this task. While no single device has delivered the 'silver bullet' in field-deployable detection, these devices have facilitated the development of a layered approach whereby detectors are employed either in parallel or in series and through a process

of elimination provide some insight into what chemical may or may not be present.

Chemometrics

A Mendlein, C Szkudlarek, and JV Goodpaster, Indiana University Purdue University Indianapolis, Indianapolis, IN, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The statistical methods that are used for measurements involving a single variable are easily calculated by hand, using a calculator, or with a spreadsheet. However, these statistical methods are not robust enough for comparing data from spectroscopy, chromatography, or mass spectrometry, where one sample (observation) has many data points at different wavelengths, times, or ions (variables). In chemometrics, multivariate chemical data (i.e., data sets containing more than one variable) are often thought of as collections of matrices where each row corresponds to a number of measurements of a single sample or single experiment. Each column represents the measurements on a single variable, such as that of a wavelength along a spectroscopic peak. By using multivariate statistical methods, the statistical significance of the differences in these patterns can be established. Chemometric methods are typically applied to reducing data, sorting and grouping, investigating the dependence among variables, prediction, or hypothesis testing. Overall, chemometrics can reduce the complexity of a large data set and make predictions about unknown samples. Chemometrics can also be used to interpret the results of forensic analyses, especially those involving pattern recognition. When using multivariate statistical techniques, replicate sample measurements should be made to allow for experimental uncertainty and determine the significance of between-sample differences.

Multivariate statistics has proven valuable for many years and numerous standard texts are available for study (see [Further Reading](#)). In fact, the underlying principles of some of these statistical methods have been known for nearly a century. For instance, the idea of principal component analysis (PCA) as a dimension reduction and data display technique originated with Pearson in 1901. In 1933, Hotelling detailed algorithms for computing principal components (PCs). The multivariate distance bearing Mahalanobis' name was introduced by him in 1936, and linear discriminant analysis (LDA) was first developed by Fisher that same year.

As it stands today, forensic scientists often rely upon visual comparisons of chromatograms and spectra when making determinations of whether known and unknown samples might have come from the same source. As a result, there is no statistical basis for determining the evidentiary value of these comparisons. Given the recent challenges to the reliability of these trace evidence comparisons, many laboratories are seeking to find ways to compare samples in a more quantitative manner. For example, multivariate statistics could address the relevance and reliability issues raised in *Daubert v. Merrell Dow Pharmaceuticals*. Chemometrics could also help with the implementation of the recommendations from the National Academy of Sciences (NAS) report on strengthening forensic science, which was issued in 2009. Specifically, Recommendations 3 and 5 can be addressed in part by the use of

chemometrics. Recommendation 3 deals with issues of accuracy and reliability in the various forensic science disciplines, and Recommendation 5 seeks to address issues of human observer bias and sources of human error (e.g., visual versus chemometric analysis of data).

Fortunately, the use of multivariate statistical analysis is a growing practice in forensic chemistry. Forensic scientists often have to identify patterns and interpret differences in data. Chemometrics makes this task more accurate, objective, and manageable. It is especially useful when the scientist is presented with large quantities of data. For example, comparing hundreds of spectra, chromatograms, etc. by inspection was never a valid scientific technique, but was widely used (and sometimes still is) until the adoption of multivariate statistical techniques by increasing numbers of forensic chemists. Multivariate statistics has been used on many types of forensic trace evidence, including accelerants, inks, fibers, smokeless powder, glass, and paint.

In general, a chemometric approach to a large data set follows a number of distinct steps:

1. Acquire data of the highest quality possible.
2. Carry out data preprocessing to remove any systematic (and unimportant) differences between samples.
3. Utilize unsupervised chemometric methods to visualize the underlying structure of the data (e.g., the number of classes).
4. Utilize supervised chemometric techniques to predict the class membership of unknown samples.

Although these steps are not always followed in all cases, they will serve as a useful outline for the discussion that follows.

Preprocessing Techniques

Preprocessing is the preparation of data before the application of chemometric algorithms. It is often required before performing multivariate statistical analyses. Preprocessing can remove noise and variation that might complicate data interpretation. However, some preprocessing can negatively impact the data, so techniques must be chosen and applied carefully.

The signal-to-noise ratio can be increased and unnecessary noise can be removed by data smoothing. Unfortunately, smoothing can cause distortions in peak height and width, can impair resolution of peaks, and can result in the loss of some features. Most smoothing methods involve creating a 'window' of a specified number of data points and using the data values within the window to estimate a 'noise-free' value for the point in the center of the window. Depending on the method used, the 'noise-free' value may be the mean or median of the values in the window, or a predicted value from a

polynomial fit to the data. Respectively, these methods are called mean smoothing, median smoothing, and running polynomial smoothing. The most common method of smoothing is running polynomial smoothing, including the Savitzky–Golay algorithm. This method is well documented and often used in instrument software.

Background correction is employed to keep varying background levels from confusing interpretation. For instance, fluorescence interference may dominate the background of a Raman spectrum. Background correction can be accomplished by subtracting a straight line or polynomial from the baseline in a spectrum. It can also be done by replacing sample vectors with their first derivative. A Savitzky–Golay algorithm exists for background correction as well, replacing each data point with the derivative of the smoothing polynomial at that point.

Normalization of spectra eliminates variations due to sample size, concentration, amount, and instrument response. It is typically conducted after smoothing and background correction have been completed. Normalization divides the values of the variables by a constant value, scaling them to a constant total (e.g., 1 or 100). The sample values may be divided by the sum of the absolute values of all intensities, normalizing the sample to unit area. The sample values may also be divided by the square root of the sum of squares of the intensities, normalizing to unit vector length.

Mean centering shifts the origin of the coordinate system to the center of the data. It eliminates constant background without changing differences in variables. It involves subtracting the mean of each variable from the related elements of the sample vectors. It essentially calculates the mean spectrum for the data set and subtracts that ‘centroid’ from each spectrum. Mean centering is often inappropriate for use in signal analysis, because the concern is variability above a baseline rather than around an average. This centering loses information about the origin of the factor space, relative magnitudes of eigenvalues, and relative errors.

Autoscaling is the use of variance scaling and mean centering. It multiplies all of the spectra in the data set by a scaling factor for each wavelength. Autoscaling is done to either increase or decrease the influence on the calibration of each wavelength. It is recommended when variables have different units of measurement or show large differences in variance. However, it can negatively impact the precision or calibration. Also, if absolute intensities are important (e.g., correspond to concentration of a sample component), autoscaling should not be used.

Agglomerative Hierarchical Clustering

The purpose of cluster analysis is to determine whether individual samples fall into groupings and what those groupings might be. No prior knowledge of groupings is known. Therefore, cluster analysis is considered an unsupervised technique in that the algorithm does not rely on any inputs from the user. Cluster analysis has been applied to a number of different evidence types ranging from inks to tapes to photocopy/printer toners.

Cluster analysis involves determining the similarities or dissimilarities between objects (i.e., distances). The items that are deemed most similar will be clustered together. The distance between objects can be measured using different approaches. The first is Euclidean distance or ruler distance. Based on the Pythagorean theorem, it is calculated as the ‘ruler distance’ between two points in an n -dimensional space. Another method is the Manhattan distance. If the Euclidean distance represents the length of the hypotenuse of a right triangle, Manhattan distance represents the distance along the two other sides of the triangle. It is generally greater than Euclidean distance. The Mahalanobis distance is an additional method for measuring similarity and dissimilarity. This method accounts for the fact that some variables may be correlated and uses the inverse of the variance–covariance matrix as a scaling factor.

Hierarchical clustering looks for the most similar or dissimilar pair of objects or clusters, then combines or divides them at each step, until all of the objects have been appropriately clustered. The information is then displayed in a two-dimensional plot called a dendrogram. There are two main types of hierarchical clustering: agglomerative hierarchical clustering (AHC) and divisive hierarchical clustering. AHC takes every object to be in its own individual cluster at first. The objects are then grouped into larger clusters, such that those in each group are more closely related than those in different groups. The most similar objects are clustered first, then those clusters are further grouped according to similarity until as few clusters as possible exist. Divisive clustering, on the other hand, starts with one group containing all of the objects and divides them based on their dissimilarity.

AHC can utilize several linkage methods. These methods include nearest neighbor, furthest neighbor, and centroid, among others. Nearest neighbor linkage, also called single linkage, joins clusters or objects based on the smallest distance between an object in the old cluster and the other objects or clusters. Furthest neighbor, or complete linkage, is the opposite of nearest neighbor and uses the greatest distance to link clusters or objects. Finally, the centroid method links clusters based on the distance between the calculated centroids of clusters rather than nearest or furthest neighbors. This method is more sensitive to outliers, as they can negatively impact the calculation of the centroid of a group.

An example of a simple two-dimensional data set containing five observations is shown in [Figure 1](#). This data set is then processed using single-linkage clustering and the dendrogram it would produce is shown.

In general, AHC is an excellent tool for initial data analysis. It allows users to examine large sets of data for both expected and unexpected clusters. However, AHC does not give any indication of which variables have the greatest influence on the clustering. And while the dendrogram is simple and standardized, and represents the entirety of the data set, it is the only view of the data available using this method. There is no way to interactively view and manipulate the dendrogram so that the user may exploit human pattern-recognition abilities.

A more realistic example is shown in [Figure 2](#). In this example, the data set consists of 50 visible spectra (400–700 nm) of various cotton fibers dyed with reactive

Figure 1 Single linkage clustering using Euclidean distance as a measure of similarity.

dyes, all of which are a shade of red/pink. In this dendrogram, there are two distinct clusters that contain the spectra from dyes C (Reactive Red 123) and D (Reactive Red 195). The remaining cluster contains the more difficult to distinguish spectra from dyes B (Reactive Red 120), E (Reactive Red 2), and F (Reactive Red 228).

Principal Component Analysis

PCA is a dimensionality reduction technique that condenses the original variables to a smaller number of significant PCs. PCA is possibly the most widely used multivariate chemometric technique as it can be used for any multivariate data set such as spectra or chromatograms.

The information gained by PCA can be visually represented in a couple of ways. The first, and most traditional form, is the scores plot. This plots the score of one PC against the score of another for each sample. Those objects that cluster closely together are similar to one another, while objects that are far apart on a scores plot are dissimilar to one another. The second method of visualizing PCA is the loadings plot. Factor loadings are plotted against each variable (e.g., wavelength). The factor loadings represent the cosines of the angle between the PC and

Figure 2 An AHC Dendrogram showing the degree of similarity between UV-visible spectra for the dyed cotton fibers shown. Note that fibers with highly similar colors also will cluster together. Ideally, the replicates from a given sample will cluster together, as is the case with fibers C and D.

each variable. Where the cosines are positive, the variables are positively correlated. Where the cosines are negative, the variables are negatively correlated. Areas where the cosine is nearly zero, the variables have no correlation.

The possible number of PCs is the smaller of the number of variables or the number of samples. To find the first PC, the axis that minimizes the orthogonal sum of squares of the data points must be found. This PC will account for the greatest amount of variance in the data set. The second PC accounts for the next greatest amount of variance in a direction perpendicular to the first PC. Each successive PC captures less of the remaining variability in the data set. Significant PCs will have larger eigenvalues, or the sum of squares of each PC or score. The sum of the eigenvalues over all PCs is equal to the number of variables present in the data set (e.g., measured wavelengths).

PCs have eigenvalues associated with them that reflect the variance, percent variance, and cumulative variance for the PC. A number of PCs must be selected to represent the data set and put through discriminant analysis (DA) if desired. If too many PCs are used, the 'noise' from extra PCs may interfere with the formation and verification of classes. To choose the correct number, one of three methods can be employed. The first method involves choosing a cumulative variance that must be met, such as 95%, and using the number of PCs that exceeds that percentage. The second method, introduced by Cattell in 1966, uses a scree plot, which plots eigenvalues against factor number. Where a sudden break in the plot occurs, this location indicates the number of significant PCs. To the right of this

location is 'factorial scree,' or debris. The third method uses the Kaiser criterion, proposed by Kaiser in 1960, to determine the number of PCs. All eigenvalues that are greater than one would be considered significant.

An example of PCA is shown below, where the clustering of elemental data is shown (as obtained by x-ray fluorescence of the backing of electrical tapes). The extent to which variance in the data set is successfully depicted in two dimensions is reflected in the total amount of variance captured by the first two PCs. In this case, almost 85% of the variance can be represented in a simple 2D scatter plot. This implies that the remaining PCs are relatively unimportant as they only account for approximately 15% of the total variance.

Discriminant Analysis

LDA is another dimensionality reduction technique. DA defines the distance of a sample from the center of a class, and creates a new set of axes to place members of the same group as close together as possible, and move the groups as far apart from one another as possible. These new axes are discriminant axes, or canonical variates (CVs), that are linear combinations of the original variables. DA is a form of supervised pattern recognition, as it relies upon information from the user in order to function. In particular, DA requires knowledge of group memberships for each sample. DA is often applied to the same sample types as is PCA, where the latter technique can be used to reduce the number of variables in the data set

Figure 3 PCA of elemental data obtained via x-ray fluorescence of electrical tape backings. Note that the six brands form five distinct clusters in a two-dimensional representation of the data.

and the resultant PCs are then used in DA to define and predict classes.

DA requires that the number of samples (i.e., spectra) exceeds the number of variables (i.e., wavelengths). If the number of samples does not exceed the number of variables, the DA calculation will fail; this is why PCA often precedes DA as a means to reduce the number of variables. Finally, the Mahalanobis distance from the sample to the centroid of any given group is calculated. The procedure for DA is somewhat analogous to that of PCA. However, instead of maximizing the sum of squares of the residuals as PCA does, DA maximizes the ratio of the variance between groups divided by the variance within groups.

Once this procedure has been followed and the new samples have been classified, cross-validation is performed to test the classification accuracy. There are a number of methods available for cross-validation. Resubstitution uses the entire data set as a training set, developing a classification method based on the known class memberships of the samples. The class membership of every sample is then predicted by the model, and the cross-validation determines how often the rule correctly classified the samples. Resubstitution has a major drawback, however. Since it uses the same data set to both build the model and to evaluate it, the accuracy of the classification is typically overestimated. When the classification model is applied to a new data set, the error rate would likely be much higher than predicted. Another method of

cross-validation is the hold-out method. This method separates the data set into two parts: one to be used as a training set for model development, and a second to be used to test the predictions of the model. Separating the data used to train the model from the data used to evaluate it creates an unbiased cross-validation. However, in situations where data are limited, this may not be the best approach, as all of the data are not used to create the classification model. Also, acquiring enough data to have appropriately sized training and test sets may be time-consuming or difficult due to resources.

One final method for cross-validation is the leave-one-out method. In this method, a sample is removed from the data set temporarily. The classification model is then built from the remaining samples, and then used to predict the classification of the deleted sample. This process continues through all of the samples, treating each sample as an unknown to be classified using the remaining samples. More than one sample can also be left out at a time. For example, 20% of the samples may be temporarily removed while the model is built using the remaining 80%. The leave-one-out method uses all of the available data for evaluating the classification model. It is time-consuming, but usually preferable.

It is common for PCA and DA to work together by first reducing the dimensionality and noise level of the data set using PCA and then basing DA on the factor scores for each observation (as opposed to its original variables). [Figure 4](#) shows the results of such a treatment on the same set of data

Figure 4 Results of discriminant analysis of the data presented in [Figure 3](#). Ellipses represent the 95% confidence limits for each of the classes. Classes that are superimposed in two dimensions (e.g., Super 33+, Super 33+ cold weather and Super 88) are more likely to be confused with one another (see [Table 1](#)).

Table 1 A “confusion matrix” resulting from leave-one-out cross validation of the data in **Figure 4**

From	To							
	<i>Super 33+ (cold weather)</i>	<i>33</i>	<i>Super 88</i>	<i>Super 33+</i>	<i>Super 33+ (2001)</i>	<i>Temflex</i>	<i>Total</i>	<i>% correct</i>
Super 33+ (cold weather)	0	0	5	0	0	0	5	0.00
33	0	14	0	0	0	0	14	100
Super 88	2	0	13	0	0	0	15	87
Super 33+	0	0	0	14	0	0	14	100
Super 33+ (2001)	0	0	0	0	10	0	10	100
Temflex	0	0	0	0	0	20	20	100
Total	2	14	18	14	10	20	78	91

Note that those classes that are most confused are Super 88 and 33+ cold weather.

shown in **Figure 3**. The extent to which DA is successful at discriminating between highly similar observations can be expressed as a ‘confusion matrix’ where the observations are tallied in terms of their original classification and the resulting classification from DA (see **Table 1**).

Conclusions

The field of chemometrics is in constant flux as new methodologies are developed and eventually tested on data sets of amazing complexity. As such, the forensic application of chemometrics will also continue to evolve. Although chemometrics has not made its grand debut into the courtroom as of this writing, the reliance of forensic scientists on databases and comparisons of known and unknown samples makes this inevitable. This is particularly true given the increasing demand for quantitative measures when expressing scientific opinions. Barriers to the full implementation of chemometric techniques in forensic science include lack of training among forensic scientists in mathematics and statistics and the need for specialized software packages to carry out calculations. Furthermore, forensic scientists must be able to explain to a jury and/or judge what the statistical procedure entailed and, most importantly, what it means. These barriers are coming down steadily, however, through education and training of forensic scientists and increasing availability of software that is either a stand-alone program or embedded within familiar spreadsheet applications. The web sites for several of these software packages are listed below. Overall, the marriage of statistics with forensic examinations is perfectly natural, but on the other hand, it is a major change in the way forensic scientists think

and work. Ultimately, it remains to be seen how this partnership will develop, but its potential impact is indisputably large.

Introduction

In today's highly mobile society, criminals often use vehicles to travel to and from the scenes of the crimes they commit. Their vehicles track over surfaces such as sand, soil, and snow, which will often retain the impressions of one or more tires. There are two forms of tire evidence potentially left at the scenes of crime. Tire marks or tire impressions are those left by the tread design. Tire tracks leave dimensional information exclusive of the tread design, and include track width, wheelbase, turning radius, as well as the relative positions of the tracks of all four tires.

Tire evidence ranges from a partial impression of one tire to a full set of tracks representing all four tires. Often details produced are sufficient to provide evidence of a vehicle's presence. Proper recovery of this evidence, through good notes and crime scene drawing measurements, photography, and casting, serves as a way of preserving the evidence for subsequent comparison with the tires and track dimensions of a vehicle.

Figure 1 gives some basic nomenclature.

Sidewall Information

Much information is molded into the sidewall. Portions of that information are of importance to the investigator and examiner, and should be noted when investigating or examining any tire. First noted should be the brand name and style name, such as Michelin XM+S 244 and the size of the tire, such as P 195 75/R 14. Also of importance is the United States Department of Transportation (DOT) number, which will usually begin with the letters DOT. Because of the worldwide tire market, this information will be found on tires made in any country. The DOT information is now required to be on both sidewalls. The DOT number will be similar to the following example:

DOT	HM	L9	ABCD	4911
Department of transportation	Manufacturer and plant code Michelin Tire Stoke-on-Trent, England	Size code	Optional symbols for manufacturer	Date of manufacturer 49th week of 2011

In this example, the two letters following the DOT number, such as HM, are symbols for the manufacturer and plant code. By

Figure 1 (a) and (b) Radial tire: basic terminology.

looking this code up in a reference source, such as who makes it and where, or searching the Internet for 'tire plant code HM,' the specific plant in this example can be identified as the Michelin Tire Company, located in Stoke-on-Trent, England. The next letter and number are the tire size code. The following four letters, for example, ABCD, are optional and are the manufacturer's symbols. The last four numerical digits are important, as they indicate the week and year in which the tire was manufactured. For example, the numbers 4911 in this example would indicate the tire was made in the 49th week (49) of 2011 (11). Tires made prior to the year 2000 only had three numbers, thus a number here of '491' would indicate the 49th week of 1991.

Retreaded tires have a slightly different DOT number on them. The retread DOT number will begin with the letters DOTR or perhaps just R. The original DOT number that was on the new tire should still be present, so it is likely that a retreaded tire will have both a DOT and a DOTR number on it. The DOTR number consists of three letters and three numbers and would be similar to the following example:

DOTR	YPY	1211
Retreaded tire	Goodyear Retread Frederickton, NB Canada	12th week of 2011

In this example, the three letters are a code to identify the retreading facility. A publication, *Who Retreads Tires*, lists approximately 5000 retreading facilities by their three-letter code. The four numbers identify the week and year of retreading.

Tire Construction

There are three basic types of tire construction that have been used in tire building: bias, bias-belted, and radial. A bias tire

will have its plies running at a bias angle across the tire. A bias-belted tire will have the same plies, but will have the addition of a belt beneath the tread area. While bias and bias-belted tires were predominant many years ago, only some large truck tires and tires for large construction equipment will likely be found to still have bias construction. Bias and bias-belted tires are less effective at reducing tire squirm, that is, the degree of contraction of the tire tread while under load. Thus, the impression left by a bias or bias-belted tire may appear to have a narrower appearance than what appears on the tire itself. A radial tire will have the plies running in a radial direction, from bead to bead. Radial tires, because of the radial direction of their plies, reduce the amount of squirm, and result in almost no difference in dimension. In an examination, test impressions of the tire made while under load on a vehicle are necessary to provide a comparable dimensional standard for comparison with a crime scene impression.

Tires are built of many components, including a liner, sidewall components, the bead, plies, belts, and tread rubber. These are assembled on a rotating and collapsible drum. After assembly of the components, the 'green tire,' whose tread rubber contains no tread or sidewall design at this point, is transferred to a mold. In the mold, under extreme heat and pressure, the various tire components will be vulcanized and bonded together. A steam-pressured bladder will inflate inside the tire and press the green tire against the surfaces of the mold. It is here that the tread and sidewall designs will be molded into the rubber.

Tire Designs and Databases

There are thousands of designs of tires, including those made for passenger vehicles; light, medium, and heavy trucks;

agricultural vehicles; off-the-road vehicles; and motorcycles. Since the 1960s, the Tread Design Guide® (Tire Guides Inc., Boca Raton, FL, USA) has offered a listing and photographs of most tire designs. This guide is published annually in hard copy form and up through 2010, a more comprehensive version on a CD-ROM known as Tread Assistant, which included over 18000 tire designs, was produced. The CD version was discontinued with the year 2011. The CD version was subdivided by the type of tire category, that is, ribbed tire, metric, lugged tire, and so on, allowing for easier search on a PC computer format. In recent years, a new database known as TreadMate® (Foster & Freeman Ltd, Vale Park, Evesham, Worcestershire, WR11 1TD, UK) has been launched. These sources provide the investigator a method of linking a crime scene impression to a specific tire design and manufacturer. Once done, additional information of relevance can be sought from the respective manufacturer if needed.

Original Equipment Tires Versus Replacement Tires

Original equipment manufacturer (OEM) tires, usually referred to as just 'OE' tires, are those which are put on a vehicle when it is manufactured. Replacement tires are those which are purchased to replace the OE tires, or other replacement tires, when they wear out. A particular vehicle with its four OE tires will not be a rare occurrence, as many thousands of those vehicles would have been sold with the same design and size of OE equipment. On the other hand, a vehicle with one or more replacement tires on it constitutes a much less frequent occurrence, as other vehicles of that type and brand are less likely to have the same combination of brand and style replacement tires. A vehicle with three or four different designs of replacement tires in a particular size constitutes a rare occurrence that would probably not be repeated, owing to the large number of available designs and sizes.

Tire Size Designations

Tire sizes have been designated in a number of ways throughout the years. The tire size designations that have been used are shown below.

Older Designations

Numeric: 6.45–14; 6.45, approximate section width in inches; 14, rim diameter; Alphanumeric: E R 78–14; E, load/size relationship; R, radial tire; 78, aspect ratio; 14, rim diameter.

Newer Designations

Metric: 195R14; 195, approximate section width in millimeters; R, radial tire; 14, rim diameter; P-Metric, P 195/75 R 14; P, passenger tire; 195, approximate section width in millimeters; 75, aspect ratio; R, radial tire; 14, rim diameter.

Aspect Ratio

The aspect ratio, otherwise known as the tire profile, is the relation of the height of a tire to its width. The appearance of a tire with a low profile or aspect ratio, such as 45, will look

flatter and proportionally wider, whereas a tire with a higher profile, such as 70, appears more conventional. Today, an increasing number of passenger cars are equipped with low-profile tires to increase traction and performance.

Noise Treatment

Tires produce noise for many reasons. Noise is generated differently as a tire crosses different surfaces, such as from asphalt to concrete. Noise is also generated as air is trapped in the void areas of the tread design upon impact with the substrate, creating a noise when it escapes. In addition, the individual tread blocks will vibrate, creating noise notable at higher speeds. Manufacturers attempt to treat and reduce this category of 'noise' by varying the pitch, or size, of the tread blocks as they are positioned around the tire. The sounds emitted by varied pitches create better harmonics than the sounds emitted by the same pitch repetitively. The industry refers to this as 'noise treatment.'

Noise treatment originally involved creating three sizes of tread blocks (design elements), that is, s, m, and l (or 1, 2, and 3). In some cases, the tread blocks may follow a 1,2,3,1,2,3,1,2,3,... arrangement around the tire. Or, they may have an arrangement of those same three sizes, but in a more random order, such as 1,3,2,2,3,1,2,3,1,1,2,3,3,2,2,1 and so forth. In other cases, more complex and varied arrangements, including more than just three different sizes, may involve a pattern such as 1,2,3,4,4,3,2,1, 3,3,2,2,2,2,3,3,4,3,2,1,1,2,3,4, and so forth. An example of such an arrangement is illustrated in Figure 2. In this example, the noise treatment consists of 64 design elements of four different sizes. They are arranged in four

Figure 2 Noise treatment example.

sequences, represented by models A, B, C, and D. The six tread-wear indicators are also included in Figure 2. The lower part of the figure represents a crime scene impression. Note that only one possible area of the tire could have produced the noise treatment in that impression. This is because the portion of noise treatment for model A plus the portion of model D, as shown in Figure 2, does not repeat elsewhere in the tire.

Tires were originally produced with a nondirectional noise treatment, that is, the pitch sequence was identical on both sides of the tire as shown below. With this form of noise treatment, the tire will leave an identical repeating sequence in either direction. Examination of a crime scene impression made by a tire with nondirectional noise treatment would not enable determination of the direction of the vehicle based on this alone.

A directional noise treatment has a pitch sequence that is different on each side of the tire; thus, it lays down a different sequence of noise treatment in each direction, relative to its direction of travel. An example of this is illustrated below. An impression made by a tire with directional noise treatment would enable a determination of the direction of the vehicle from the impression, as long as the position of the tire (left or right side of vehicle) and the way the tire was mounted on the wheel (which side is out, which side is in) are known. Directional noise treatment should not be confused with a directional tire, which must be mounted in a prescribed way and whose direction can be visually distinguished.

The noise treatment of tires is used whenever possible during the examination of tire impressions, as it assists in locating the possible position on the tire that could have made a particular impression. An average passenger or light truck tire may have 2 m or more of tread in a full circumference impression. A crime scene photograph or a cast of a tire impression may only be 0.25–0.5 m in length. If it is of sufficient length, the crime scene impression will only match one location around the circumference of the tire that made it. Once that position is located, it will then be additionally examined for evidence of wear and acquired individual characteristics. Recovering longer segments of impressions at crime scenes allows for a more specific determination of the portion(s) of the tire that made the impression. Every examiner who conducts forensic tire impression examinations should be knowledgeable about tread design noise treatment and how it is significant in the comparison process.

Tread-Wear Indicators

Tread-wear indicators, also known as wear bars, are required in tire manufacturing. On tires 13 inch. or larger in diameter, tread-wear indicators must appear at least six times around the tire's circumference. For tires having a 12-inch. diameter or smaller, there must be at least three tread-wear indicators. They consist of rubber bars which are raised 2/32nds of an inch

(0.16 cm) above the base of the grooves. In this way, as the tire wears down, the wear indicators will appear as bald strips across the remaining tread design. Tread-wear indicators are visible in a two-dimensional impression only if the tire is worn down to that level. They may be visible in three-dimensional impressions if the tire had produced a deep enough impression in the substrate. Tread-wear indicators will occur in different portions relative to the noise treatment of that tire. Each tread-wear indicator will therefore be in a different portion of the noise treatment arrangement (Figure 2). This can be of further assistance in locating the precise portion of the tire that made the impression.

Known Standards of Tires

Known standards of tires fall into two different categories. They include those obtained for tires that differ in design from the questioned impression such as police and emergency vehicles and thus can easily be eliminated, and those that are similar in design and must be exhaustively compared with the impression with regard to the characteristics of tread design, dimension, wear, and individual characteristics.

For those that fall into the category of being of a different design to the questioned impressions, elimination standards need only consist of a digital photograph or adhesive lift of a short segment of the design. In addition, the sidewall brand name and style and size should be noted, as well as what vehicle the tire is associated with.

If the tire is similar in design to the questioned impression, the actual tire is required. If the actual vehicle is seized, that vehicle can be used to produce the known standards. If the tires alone are seized from the vehicle, each tire's position on the vehicle (left front, right rear, etc.) and the side of the tire facing out (white wall side or black wall side) should be noted and should be marked directly on the tire before it is removed from the vehicle. To assist in the comparison process, known full circumference impressions of the tire must be obtained to assist in that comparison process. This is accomplished with inks or powders on long pieces of solid core chart board, or on clear polyester film placed over the chart board. This may be done on the actual suspect vehicle, or on a vehicle which will accommodate the tire.

Cases involving large trucks or trailer rigs should utilize those trucks or trailers when obtaining the known impressions. Tires should not be removed from any trucks that have double tires mounted on each side if they are to be compared with double tire impressions from the scene of the crime. Only after adequate known impressions are taken should they be removed for a more detailed examination. This is because the relative position of the tires to one another, as they have been mounted, is highly significant. Removal of the tires would lose that important aspect of the evidence.

Examination of Tire Impressions

Forensic examination first evaluates the general class characteristics of the tread design and dimension. If the tread design of the questioned impression is visibly different from a particular tire, that tire can be eliminated. If the tread design is similar, a more detailed examination must take place and requires full circumference impression standards of that tire. These must be

made on a vehicle under load. With the full circumference impressions, the specific tread design and its dimensions, including agreement or disagreement of the noise treatment, can be compared. This examination of the tire will require superimposition of the known impressions over the questioned impression(s). This assists in locating the specific design, size, and noise treatment features, as well as characteristics of wear and individual characteristics. If the design, size, and noise treatment correspond, further comparison of the tire or tires proceeds. Any wear characteristics, such as worn-away tread pattern, sipes, irregular tire wear, and tread-wear indicators, will assist further in locating the possible area or areas of the tire that could potentially have made the crime scene impression.

Finally, any randomly acquired individual characteristics such as scratches, tears, cuts, stone holds, and sipe damage that appear on the tires and are clearly evident in the impression are examined. Their presence on the tire is random in nature and results in a tire that differs from others of the same tread dimension and design. The presence of random individual characteristics will contribute toward, or be the basis for, identification of that tire as making the crime scene impression.

When making examinations between a crime scene tire impression and a suspect tire, a range of conclusions is possible. It can be concluded that a tire positively made an impression. This would occur when the crime scene impression and suspect tire correspond in design, noise treatment, dimension, condition of wear, and also share sufficient randomly acquired individual features. In less conclusive examinations, it is still often possible to associate a crime scene tire impression as sharing significant features in common with the suspect tire, such as design, noise treatment, dimension, and condition of wear. Because of the large number of possible designs and sizes and conditions of wear, particularly when dealing with replacement tires, this category of conclusion is still valuable and highly relevant. Finally, substantive differences in class characteristics of size or design in the noise treatment or significant differences in the condition of wear can contribute toward, or be the basis for, elimination of the tire.

It is noted that the absence of random individual characteristics, either in the crime scene impression or tire, does not constitute a basis for nonidentification for a few reasons. The impression may not have retained sufficient detail to allow for examination of those areas, or sufficient additional mileage on the vehicle may have worn off old characteristics or it may have acquired new characteristics.

Vehicle Dimensions and Turning

Tread Design Width

Tread design width, also known as “arc” width, is the distance between the edges of the tire tread. This is sometimes difficult to measure, owing to uneven wearing of the tire, the incompleteness of some impressions, and other factors.

Track Width (Stance)

Track width, also known as “tire stance,” is the distance measured perpendicularly from the center of one wheel, tire, or impression to the opposite wheel, tire, or impression. In most vehicles, the track width of the rear wheels is different from that

of the front wheels. The rear tire track measurements will always record in the substrate accurately, whether going straight or while turning, as they are attached to a fixed axle. The front wheel track measurement will only measure accurately if the vehicle is going straight, but will change dramatically if the vehicle is turning as the resulting tracks will be closer together. Consequently, the front track measurement is less reliable. With regard to both front and rear measurements, it should be noted that in substrates that are uneven, or in cases where the impression does not record sufficiently, it becomes more difficult to measure track width accurately. Additionally, if custom wheels of different dimensions have been placed on the vehicle, or if the wheel mounting changes, as in the case of mounting wheels in a reversed position, the track width for that vehicle will be changed from its original specifications.

The track width on trucks that have two tires mounted on each side is measured from the point that is the direct center between the two wheels on one side to the center of the two wheels on the opposite side. Should trucks of the same type, model, and year be configured with different axles or different wheels, the track width will be changed. Track width and wheelbase measurements are illustrated in [Figure 3](#).

Wheelbase

The wheelbase of a vehicle is the dimension measured longitudinally between the center of the front and rear wheels. A close equivalent to the wheelbase can be measured as the distance between the leading edges of the front and rear tire tracks, as in the case where the tires have sunk in the ground or have turned. Measurements should be taken from each side of the impression, as the leading edge of a tire, when turning, will cause this measurement to increase or decrease, depending on which side of the tire is used for the measurement.

Figure 3 (a) Track width: the dimension measured between the tire and wheel centers. The front and rear track widths for most vehicles are not the same. (b) Wheelbase: the dimension measured longitudinally between the center of the front and rear wheels.

Turning Positions

Tires positioned at the rear of a vehicle, when the vehicle is turning, track to the inside of the respective front tires. This is very important to understand when reconstructing the position of tires at a crime scene and later linking similar positions to the respective tires. This is illustrated in [Figure 4](#).

Turning Diameter

Every vehicle has a turning radius or turning diameter that represents the smallest radius that that particular vehicle type can turn in a circle. A crime scene impression with front wheel tracks that turn sharply can be measured and used to include or eliminate vehicles which can or cannot turn in that diameter or less. The measurement of the track should be made at its outer margin. The following formula and [Figure 5](#) illustrate this procedure.

Figure 4 Turning positions. When the vehicle is turning, the rear tires track to the inside of the respective front tires.

Figure 5 Turning diameter. Measurements are taken from the outer edge of the arc made by the outermost front tire. See text for details.

$$\text{Turning diameter} = (B^2 \div A) + A$$

For example, in [Figure 5](#), if line x to x' equals 9 m, then B equals 4.5 m, and if A equals 3.1 m, then:

$$\begin{aligned} \text{Turning diameter} &= (4.5^2 \div 3.1) + 3.1 \\ &= (20.25 \div 3.1) + 3.1 \\ &= 6.53 + 3.1 \\ &= 9.63\text{m} \end{aligned}$$

Recovery Methods Specific to Tires

Photography

The general crime scene and examination quality photography of tire impressions at the scene of a crime is carried out in the same manner as for footwear marks, with one exception. That exception involves the need sometimes to document a tire impression which is longer than that typically captured in a single examination quality photograph. This normally applies to impressions that are in excess of 0.5 m in length. Impressions longer than 0.5 m require a sequence of overlapping photographs, which upon processing and enlarging can be combined to recreate the long tire impression for comparison. To take sequenced photographs of a long tire impression, a rigid meter stick should be laid alongside the full length of the long impression. The meter stick should be placed so it is on the same level or plane as the bottom of the tire impression. Once laid down and once photography begins, it should not be disturbed. It will not be used as a scale but only to help reconstruct the sequence and later splice the photographs together. A more accurate scale can be positioned on top of the meter stick in each individual tire impression segment photographed and moved accordingly as the sequence of photographs are taken along the length of the long impression. The photograph of each section should be approximately 0.5 m and overlap the previous photography by 6–10 cm. With this method, a long impression can be photographed in several segments, each accurately representing the respective section. The natural size enlargements of the segments can be assembled together to recreate the full impression. This method is illustrated in [Figure 6](#).

Casting

Dental stone casts of three-dimensional tire impressions are invaluable for examination and, if properly taken, will provide the most detailed and accurately sized representation of the tire impression. Casts capture the contours and uneven qualities of the tire impressions, which are not always apparent or able to be recovered in photographs. In deeper impressions, sidewall treatments are often recorded, revealing potentially important information. For this reason, the casting material should be allowed to completely fill and overflow out of the tire impression. Because of the noise treatment, it is also desirable to cast the largest tire segment as is reasonably possible. Impressions at crime scenes that are 1 m or less should always be cast in their entirety. Larger casts can be made for longer impressions but as they increase in length, particularly if they are deep, their size and weight will rapidly become unmanageable. In cases

Figure 6 Documenting a long tire impression photographically.

involving long segments of one or more tire tracks from a vehicle, at least one cast, a minimum of 1 m long if possible, should be made of the best portion of each separate track. Additional casts, particularly of the more detailed segments of the tracks, should be considered, if possible. On the back of the cast, information about each impression and its relative direction should be noted. In addition, general scene photographs should be taken of the casts, once they are all poured but before they are lifted from the scene. This will also document the position and direction of the casts. Tracks made by trucks with dual assemblies, that is, two tires mounted side by side, should be cast as one unit. This will assure that a record of the exact relative position of those tires to each other is made.

Retreaded Tires

Retreaded tires are predominantly used on medium and large trucks, where the monetary savings between new tires and retreaded tires is significant. Some retread designs for truck tires closely simulate the design of OEM tires.

Retreaded tires are made using one of two processes. Each of these processes leaves characteristics that reveal that the tire is a retread and some may also contribute to the individuality of the tire. They are known as the 'mold cure' process and the 'precured' process. The mold cure process uses strips of raw rubber that are applied to the used tire carcass, which is then placed into a mold where the new tread is formed. The traditional precured process uses premolded rubber containing the tread design, which is then bonded to the original tire carcass and will contain a splice joint, revealing where the precured tread rubber was joined together. The position of this joint will be different from most other retread tires of this design, and will be very significant should evidence of it be retained in a

crime scene tire impression. Some newer precured processes use a continuous band of tread that is stretched around the tire carcass, eliminating the splice joint.

Retread tires for passenger vehicles are not made in the quantities that original molded tires are made. The occurrence of a particular design of a retreaded tire on a vehicle is therefore less frequent and thus more significant. Information to support the production volume of a particular tire can be obtained by contacting the retreading facility, via the retread code on the tire. A retread DOT code, explained earlier, should be present on the retread tire.

Glossary

Die lines Striations left on the outer and inner surfaces of plastic film, which are formed by damage to the die.

Hairline marks Striations are left on the outer and inner surfaces of plastic film, from the die and mandrel, and rollers used to extrude the molten plastic.

Inference Intellectual process of reasoning that aims at deriving logical conclusions from premises.

Intelligence (forensic) Result of continuous and iterative processes that aims at transforming the raw data into a form that is suitable for making decision.

Tigerstripes Horizontal streaks across the plastic film, which may be formed during the stretching out of the film, by the pulling machinery, and the pressurized air used for this purpose.

Weld lines Striations are left on the outer and inner surfaces of plastic film, which are formed by impurities caught in the die.

Introduction

Plastics, in general, and plastic bags and films, in particular, are in common use in a large variety of daily activities. As a result, they are commonly employed in relation to the commission of crime, the most obvious examples being packaging material in drug trafficking and explosion cases. They may also be used to conceal body parts of a victim. The ability to compare, link, and identify plastic bags or films from crime scenes with similar items in the possession of suspects or found in serial cases is of prime importance in forensic science, whether it is for evidential or intelligence purposes. Rather than using plastic bags only for specific comparisons, they can be systematically compared to obtain intelligence. Indeed, it can be presumed that the same packaging materials for wrapping illicit drugs or explosives would be used by a producer or a specific group of people. As a consequence, linking the different plastic bags could provide information about specific distribution networks. In general, this examination relies on optical, physical, and chemical techniques. The combination of identifying features allows plastic bags or sections of plastic film to be compared and conclusions to be drawn about their origin or relationship to each other.

It is the aim of this article to present and discuss the examination of plastic bags, and more specifically, the use and value of some of their physical features often known as 'plastic bag striations.'

Background

Awareness of the principles and processes underlying plastics chemistry and manufacture is necessary in order to appreciate the nature and value of the characteristics, which will be encountered during an examination and comparison of such items.

Plastics Chemistry

Plastic was originally developed as a cheap substitute for natural materials, such as wood and metal. Since then, the industry has grown to produce plastics that are often superior to the products they were developed to replace. Although they create pollution problems and can have harmful impacts on the environment, they are still widely used due to their functional, strong, and cheap characteristics.

Plastic is a by-product of the petroleum industry, and the principal raw materials are organic chemicals used as monomers and plasticizers, and specialty chemicals that are used as additives to modify the properties of the plastic produced. Monomers are low-molecular weight molecules, which are joined together by strong covalent bonds in a chemical process called polymerization, to form a chain of repeating monomer units. This chain has a high molecular weight and is called a polymer. Polymer resins are grouped by their monomer unit. The atoms along the center of the polymer chain are usually carbon atoms, and these form the backbone of the macromolecule. The atoms or groups of atoms on the side of the chain are called side groups or branches. One of the most simple and commonly used polymers is polyethylene, which is formed via the polymerization of the monomer, ethylene (**Figure 1**).

Polyethylene, commonly called polythene, is versatile and can be either flexible or rigid, depending on its density. The density of a polymer is determined by the level of chain branching. As monomers link together, they sometimes form branches from the main chain. If there are only a few branches, the polymer chains pack closely together producing a high-density, stiff plastic. Chains with a higher number of branches lie further apart and produce a low-density plastic, which is therefore more flexible. Plastic bags and films are commonly made from a type of polyethylene. High-density polyethylene is used in the production of freezer bags, crinkly shopping bags, and milk bottles, whereas low-density polyethylene is

used to manufacture cling films and other articles, including garbage bins.

Like polyethylene, polypropylene is a simple polymer, formed by the polymerization of the monomer propylene. It is also used in some clear films for food and microwave packaging (Figure 2).

Another more complex polymer is polyvinyl chloride (PVC), which is formed via the polymerization of the monomer, vinyl chloride. PVC is naturally rigid, but can be made flexible by the addition of a plasticizer, such as dioctyl adipate (DOA). Similarly, polyvinylidene chloride (PVDC), formed from vinylidene chloride, uses dihexylazelaate plasticizer. However, polymers which require the addition of plasticizers are being used less frequently in packaging materials traditionally used for food, as it has been found that some plasticizers may migrate into food products (Figures 3 and 4).

Polyethylene terephthalate (PET) is a relatively short-chain polymer with high strength and good resistance to acids, alkalis, bleaches, detergents, and heat. It is also a good barrier to carbon dioxide, and is therefore well known for its use in carbonated soft-drink bottles. Another use is in cook-in oven bags (Figure 5).

The above polymers are all classified as thermoplastics. Thermoplastics are polymers which change form when heated, to allow molding into a desired shape. If thermoplastics are reheated, they return to a liquid form. This allows processes, such as recycling, to be carried out on these polymers.

Figure 1 Chemical structures of ethylene and polyethylene.

Figure 2 Chemical structures of propylene and polypropylene.

Figure 3 Chemical structures of vinyl chloride and polyvinyl chloride.

Polyamide resins, or nylons, are polymers that consist of a repeating amide unit, and are known for their toughness and high temperature resistance. Unlike the polymers mentioned thus far, once shaped, they will not change shape or form, even when heated, and are therefore classified as thermosets. For this reason, they have also been used in oven bags (Figure 6).

A number of additives, such as fillers, stabilizers, and pigments, are often mixed with polymers in a process known as compounding. These modifiers may increase the material's strength, reduce its cost, increase its heat and light resistance, impart flexibility, or add color.

Copolymerization, which involves linking together two or more polymers, is sometimes carried out as an alternative method for changing the properties of the plastic. Ethylene vinyl acetate (EVA) is such a copolymer. EVA is a combination of polyethylene with polyvinyl acetate. Polyvinyl acetate is resistant to oxidation and inert to the effects of ultraviolet (UV) and visible light, and when added to polyethylene, it imparts these favorable characteristics. Because of these properties, EVA is used in plastic food packaging, where prevention of oxidation and light degradation are particularly important (Figure 7).

In recent years, degradable polymers have been introduced to replace polyethylene bags in order to reduce the harmful impact on the environment. Degradable materials are able to break down by bacterial (biodegradable), thermal (oxidative), or UV (photodegradable) action. Five different types of degradable polymers exist:

Figure 4 Chemical structures of vinylidene chloride and polyvinylidene chloride.

Figure 5 Chemical structure of polyethylene terephthalate.

Figure 6 Chemical structure of nylon 66.

- Biodegradable polymers are those that mostly decompose into carbon dioxide, water, methane, and inorganic compounds by enzymatic action of microorganisms.
- Oxo-biodegradable polymers are those that undertake controlled and accelerated degradation when combined with an additive.
- Compostable polymers are those that break down through the action of microorganisms and quickly reach complete conversion into carbon dioxide, water, methane, and inorganic compounds.
- Photodegradable polymers are those that decompose through the action of UV light.
- Water-soluble polymers are those that dissolve in water and then biodegrade through the action of microorganisms.

Plastic Bag and Film Manufacture

The basic manufacture process starts with virgin or reprocessed resin pellets. The resin pellets are placed in an extruder (see Figure 8), which is cylindrically shaped, and then heated to approximately 250 °C. Any pigments or other additives are then mixed in with the polymer to form a homogenous, viscous fluid. At this point, the polymer is forced through a screen filter attached to the end of the extruder. This serves to remove any large impurities from the mixture.

After passing through the screen, there are two possible alternatives. The polymer can undergo either cast or blown extrusion.

Cast Extrusion

In cast extrusion, the polymer is forced through a straight die, in the form of a horizontal slit, which forms a flat sheet of film, with its thickness equal to the size of the slit. It is then cooled, drawn off through rollers, and wound onto a roll.

Blown Extrusion

In blown extrusion, which is the more common type of extrusion, the molten plastic is extruded between a ring-shaped die and a mandrel, which is a rod at the axis of the die. This type of

Figure 7 Chemical structures of vinyl acetate and polyvinyl acetate.

Figure 8 Cast extrusion of a polymer film.

extrusion forms a plastic tube. Pressurized air is blown through the mandrel to the inside of the plastic tube to allow the tube to be stretched to the desired size and thickness. The tube is then drawn upward, cooled, and flattened (Figure 9).

Generally, blown extrusion is used for plastic bag manufacture, but cling film may be manufactured using either blown or cast extrusion. If blown extrusion is used for cling film manufacture, the extruded tubular film is slit to form a single, wide sheet, which is then rolled onto a cardboard former and cut into individual rolls. To produce resealable bags by blown extrusion, the die has grooves on its sides to form the sealing strips.

After blown or cast extrusion, the plastic sheet is either wound onto a roll or passed on for further manufacture, which may occur at a different location. The production of bags following extrusion varies greatly depending on the type of bag desired. The plastic sheet may undergo printing, folding, gusseting, addition of handles, heat sealing, and cutting. The process becomes more complex as the bag itself becomes more complicated.

Physical Features

A number of physical methods have been developed to examine plastics commonly used for packaging drugs. These physical methods generally depend on identifying characteristics that are permanently left on the bag or film during the manufacturing process. These identifying characteristics can be used to match plastic packaging to packaging found in a suspect's possession, or more broadly, to show that the packaging comes from a certain batch or brand. Examples of such identifying characteristics are striations, pigment bands, and 'tigerstripes.'

It is commonly observed that striations are left on the outer and inner surfaces of plastic film, from the die and mandrel, and rollers used to extrude the molten plastic. These are called hairline marks, and are separated into die lines (formed by damage to the die) and weld lines (formed by impurities caught in the die). If the die and mandrel are slowly rotated during production, the striations created will be slightly spiraling. On the other hand, if the die and mandrel are not rotated, the nonspiraling die lines may result in residues building up and wearing away, leaving slight random streaks or gauge variations in the plastic (Figure 10).

Pigment bands, which are caused by the inadequate mixing of dyes or pigments with the melted resin, may sometimes occur. They generally run in the direction of film production. These are useful characteristics for linking a large number of items to a common source.

Figure 9 Blown extrusion of a polymer film.

'Tigerstripes,' or horizontal streaks across the plastic film, may be formed during the stretching out of the film, by the pulling machinery, and the pressurized air used for this purpose. These markings are useful for identifying items that are close to one another in the manufacturing sequence (Figure 11).

In addition, random impurities in the plastic, such as carbon material, resin, pigment, or grit, which were not removed in the filtering step, result in dark or light spots of plastic, or 'fisheyes,' in conjunction with radiating vertical streaks, known as 'arrowheads.' Both characteristics are useful for identifying items manufactured close to each other in the manufacturing sequence (Figure 12).

Some plastics which have undergone a surface chemical treatment may have delicate surface characteristics, which are easily damaged features and are highly individual. Printing on plastic bags can sometimes be shown to have certain small defects, such as extra dots of ink, that can be used to show that the bags were manufactured on the same production line (Figure 13).

Where heat sealers have been used to cut or seal plastic, it is possible to examine the distinctive impressions made in the seal by the fabric or teflon covering the heated metal strips on the heat sealer. In addition, cutting devices incorporated in sealing machines, or separate cutting devices, may leave characteristic snag marks or slight changes in direction of cutting which can be identified.

Figure 10 Striations ('Die' and 'Weld' lines).

Figure 11 'Tigerstripes.'

Where bags are torn from a roll by perforations, an examination of the perforations can be made. If a notched blade is used to make the perforations, it will consist of a line of cuts which looks like a dotted line, whereas if a saw-toothed blade is used, the perforation will be a line of curved or V-shaped cuts.

Surface scratches and roller marks can be left on plastic bags either during manufacture, while being passed over rollers and other surfaces, or after manufacture, during handling of the bags. Scratches on two pieces of plastic can be compared side by side and can be used to identify a common source. In addition, some cling films and plastic bags have distinct surface textures or patterns, which can be used to discriminate samples (Figure 14).

Figure 12 A 'fisheye.'

Figure 13 Printing defect on Glad Snap-lock Bag.

Figure 14 Surface pattern on sandwich bag.

Where pieces of plastic have been torn from a larger piece of plastic film, or from a plastic bag, it may be possible to carry out a physical fit of the torn pieces.

The combination of these physical features along with the color, printing, dimensions, thickness, and the arrangement and type of sealing, cut edges, and perforations (construction characteristics), allow plastic bags or sections of plastic film to be compared and conclusions to be drawn about their origin or relationship to each other.

Methods for Visualization of Physical Features

A number of methods have been described for visualizing the characteristic marks discussed above. These methods include

- physical matching of cut or torn edges
- transmitted, incident, and oblique light
- interference grid
- shadowgraph photography
- schlieren photography
- crossed polarizing filters
- powdering.

Physical Matching of Cut or Torn Edges

There is no better evidence of common source than a demonstrated physical fit between torn edges of two samples of plastic. Also, matched cut edges can prove that two samples were manufactured consecutively in a sequence. This can strengthen the observations made using some of the other techniques.

Transmitted, Incident, and Oblique Light

These methods are very straightforward and constitute the early stage of any plastic bag examination. The only differences between the techniques are simply variations in the position of the light source. Transmitted light is useful to render visible characteristics, such as pigment bands and fisheyes, found in pigmented plastic bags. Oblique transmitted light is best suited for transparent rather than pigmented films. Incident light reveal features on the surface of the plastic such as scratches and printing. In all cases, the characteristics are easily recorded by photography.

Incident and transmitted light microscopy can be carried out using a good quality stereo microscope. In transmittance

mode, most of the light passing through the bag or film will not enter the objective lens, whereas light which is deflected by discontinuities, surface scratches, or markings on a heat seal will enter the objective. With the use of incident microscopy, it is possible to observe the details of any printing and the texture of the plastic.

Interference Grid

In this method, a grid of alternating black and white lines is illuminated behind a sample. The discontinuities in the plastic interfere with the appearance of the grid, allowing the characteristics to be visualized. These are then photographed and can be compared. Although the quality of the result is not high, the advantage of this technique is that it is nondestructive and cost-effective as the only equipment required is the black and white grid, a light source, and a camera.

Shadowgraph Photography

Shadowgraph photography is a simple method for visualizing and comparing extrusion marks, heat-sealed edges, and cut edges on polythene sheet and polythene bags. The method exploits the way light can be refracted when passing through transparent materials of variable shape and density. A simple example is the way that a visible rippling effect is visible in the appearance of items viewed through the heated air above a candle flame. The advantage of this method is that it is non-destructive, that is, it leaves the sample unchanged and available for further analysis.

A shadowgraph is made by light passing through the plastic film so as to make an image on a screen. The inhomogeneities in the plastic film, scatter or deflect the light out of its normal path to the screen, leaving a shadow.

Technically, the shadowgraph obtained on the screen can be recorded photographically or electronically. A high-contrast photographic film or paper can also substitute the screen. The use of a condenser type photographic enlarger constitutes a variation of the technique. In this instance, the polythene sample is placed where a negative would be positioned for enlargement between a light source and a lens system. The lens system serves to project the focused image at a desired magnification. The image can then be recorded as aforementioned (Figure 15).

Figure 15 Shadowgraph photography.

Schlieren Photography

Schlieren photography is closely related to the shadowgraph technique aforementioned, although it is more difficult to set up. The difference in Schlieren photography is that the light scattered by the inhomogeneities is focused on the screen by the use of lenses or mirrors, together with knife-edge filters.

Light from a point source pass through a collimating lens and is then collected and focused by a second lens or by using two spherical mirrors. The plastic film to be examined is placed in the area between the two lenses, which is known as the Schlieren Field. A knife-edge filter is positioned at the focal point of the second lens and carefully adjusted across the beam of light, restricting the undeviated light while enhancing the light scattered by the inhomogeneities in the plastic film. The image is recorded in the same way as for shadowgraphs. Castle et al. detailed an optical bench used by the Metropolitan Police Forensic Science Laboratory for shadowgraph and Schlieren photography (Figure 16).

Crossed Polarizing Filters

This technique takes advantage of the fact that polymer chains become oriented during the extrusion process. Two linear polarizing filters are placed at 90° to one another (crossed polarizing filters). The samples to be examined are placed between the two filters and rotated to an angle of 45° relative to the crossed polars. The samples show patterns of color if the plastic is birefringent, indicating variations in birefringence and/or in thickness. Machining marks present on plastic bags or film, such as scratches and roller marks, can also be visualized by this method. A large polarization table can be used so that multiple bags can be viewed. Alternatively, the patterns can be photographed and the photographs examined and compared at a later time.

Powdering

Some authors advocate the use of powdering to enhance surface features on plastic film. This can be achieved by carefully misting fingerprint black powder applied by blowing, or using a magnetic wand or a traditional fingerprint brush. However, this method can interfere with the search for fingerprints on the bags and a subsequent chemical analysis. For this reason, and also since other nondestructive methods exist, it appears sensible to avoid powdering, or, at least, apply the other methods first.

Chemical Methods

A wide variety of chemical methods can be applied to the examination of plastic packaging materials. These methods characterize the makeup of the plastic bags or films under investigation, including the polymer base, along with the dyes and pigments. They provide molecular and elemental information, which is extremely valuable for comparison purposes. Common methods include UV-visible spectrometry with or without microscope attachment, Fourier transform infrared (FTIR) spectroscopy, pyrolysis gas chromatography (Py-GC), thin layer chromatography (TLC), X-ray fluorescence (XRF) spectroscopy, differential scanning calorimetry (DSC), gas chromatography-mass spectrometry (GC-MS), and neutron activation analysis (NAA). It is beyond the scope of this article to discuss these analytical techniques in detail; suffice to say that chemical characterization constitutes a necessary step in the protocol for analyzing plastic bags or film. These methods can easily differentiate samples which appear visually similar in the first instance. However, it should be pointed out that chemical methods allow the samples to be identified at the class level only. The value of matching chemical profiles, therefore, is assessed by the forensic scientist on the basis of the rarity and permanence of the major and minor materials making up the plastic bags, including the base polymer, additives, pigments, and dyes.

Protocol for Forensic Examination of Plastic Bags and Films

The forensic examination of plastic bags and films follows the general stepwise method, from the general to the particular and from least to most destructive techniques. The actual individual method applied depends greatly upon the resources of the laboratory, the case material (colored plastic, transparent plastic, minute sample, etc.) and to some extent, on the personal preferences of the examiner. However, in any case, a stringent optical examination is applied first.

At first, the features to be taken into account are the general packaging type, the presence of any printing or labels, and the color and construction characteristics of the packaging. A description of any printing or labels should be recorded, along with the dimensions of the feature. The importance of optical examination is demonstrated in a study conducted by Causin et al. where one third of the samples collected could be readily

Figure 16 Schlieren photography.

differentiated by optical examination. The number of seams, folds, cuts, perforations, and seals, and their position in relation to each other, should be noted. The dimensions of the packaging should be measured with a ruler and a micrometer (in particular for the thickness). Appropriate measurements include length, width, thickness, length of hem (portion of the bag past the bottom seal), and length above top seal. A general photograph of the packaging should be taken, including a scale. At this stage, close-up photographs may be taken of labels, printing, sealing mechanism, and any relevant features present on the plastic bag.

A low-power stereomicroscope may be used to observe and photograph minute details, such as printing defects. The weight should be measured on an analytical balance, and a weight/area calculated.

A multiwavelength light source, such as the Polilight lamp (Rofin, Australia), should be used to view colored or printed packaging, to help visualize any characteristic feature, such as luminescence. The light source should be slowly scanned over the packaging, using white light and light from 350 nm to 650 nm, and any observations noted. This process is repeated numerous times while viewing through a number of UV and colored filters. This step may be left out for colorless samples.

Some of the methods for visualizing physical features described above should then be used. To this end, cross polarizing filters which are relatively simple to use and which will usually provide extremely high discrimination, are recommended. Both colored and colorless drug packaging should be viewed between two linear crossed polarizing filters, with transmitted light from a light box. Observations should be recorded and a photograph may be taken.

The use of shadowgraph and/or Schlieren photography is also recommended, given the value of these techniques for producing fine detail completely invisible to the unaided eye. These techniques are more complicated to set up, but are particularly useful where the plastic samples under examination exhibit poor birefringence colors under the crossed polarizing filters (a good example is cling film).

By comparison, the interference grid technique generally produces poorer results, however, it should not be ruled out as it has an obvious advantage in simplicity and low cost.

When the optical examination and physical measurements are completed, chemical analyses may be carried out. In this context, both the molecular and elemental characterizations are generally required. The choice of an individual technique mainly depends on the resources of the laboratory.

Roux et al. proposed a sequence of analysis for plastic drug packaging materials. This sequence includes optical examination, measurement of dimensions, general and close-up photographs, measurement of thickness and weight, optical examination using the Polilight, followed by the crossed polarized light technique, UV-vis analysis, and finally an FTIR analysis. They observed that the optical examination was the most effective step for discriminating samples.

Value of Plastic Bag Evidence

There are a number of conclusions that may be drawn after completion of the sequence of analysis. These conclusions include whether the bags or pieces of film were or were not

- manufactured from the same type of polymer;
- manufactured from the same chemical batch or formulation of a certain polymer;
- produced by the same machinery; and
- directly connected during manufacture (i.e., adjacent on the same large piece of plastic film before cutting into bags or lengths of film).

A general caution should be taken heed of, when carrying out any of the above analyses on plastic packaging. There are a number of possible ways that the product can be manufactured. The company that manufactures the end product may also produce the polymer resin from which it is manufactured, that is, the company manufactures the product from start to finish. However, this is a rare situation. The company may buy the polymer resin and then manufacture the product. On the other hand, the company may buy lengths of plastic tubing, and then cut bags or lengths of film from this tubing. In some cases, the bags are bought premanufactured, and are simply packaged by the company before sale.

If all of these factors remained constant for a single product, there would not be a problem. The problem lies in the fact that the companies, which produce plastic packaging, often have several suppliers for the same ingredients or processes. Companies may change suppliers for a certain product or ingredient depending on cost, reliability, and a number of other factors. Sometimes an entire process may be changed due to technological improvements in machinery, or chemical ingredients may be changed due to health, safety, or environmental concerns (e.g., the change from PVC to polyethylene in clingwraps).

This dynamic can be an advantage during the comparison process when the aim is to discriminate similar but unrelated specimens. However, it is also a challenge during the early stages of the investigation when the identification of possible sources or manufacture is required and no comparison sample is available. Nevertheless, the systematic comparison of specimens (in particular in illicit drug trafficking) coming from different cases can contribute to an enhanced understanding and increased knowledge of the structure of criminal activity. For instance, an application of the analysis and interpretation of packaging materials used in illicit drug trafficking was reported in three articles written by Huttunen et al. It was mentioned that the analysis of packaging could assist law enforcement to gather intelligence and draw further inferences about the trafficking of illicit drugs.

Furthermore, plastic bag evidence can be extremely valuable when interpreted appropriately. For example, in a case where a large drug seizure has been made, and on searching a suspect's house or vehicle, some plastic bags or film are found, it is then possible to compare the plastic packaging found containing the drugs to the plastic found in the suspect's possession. The visualization of machining marks can either show that the plastic packaging has completely different marks and is unrelated, or that the packaging has similar marks and has been manufactured on the same machinery at around the same time, or that the packaging was joined together during manufacturing, before cutting into bags or smaller lengths of film, and is therefore most probably from the same packet after manufacture.

However, it is important to be careful when making conclusions in this manner. All the bags in one packet may not be

in sequence. Also, during quality control procedures at the manufacturing plant, some bags may be removed from the packet for testing and replaced with bags from another packet or batch.

Therefore, if a plastic bag discovered in a suspect's possession is found to match a bag containing illicit drugs, it can be said that the bags were manufactured on the same machinery at around the same time, or in some cases, that the bags were directly connected during manufacture, and were therefore from the same packet of bags. However, if the plastic bag discovered in a suspect's possession does not match the plastic bag containing illicit drugs, it cannot be said that the bags definitely did not come from the same packet.

Glossary

Bare footprint mark The weight-bearing impression of the human foot, either barefoot, socked foot, or left inside of footwear. The impression can be two or three dimensional and created in a single step or through multiple steps of the foot in one location, such as inside of footwear.

Barefoot morphology comparison A comparison conducted of the shapes of the weight-bearing impression of the foot, barefoot, socked foot, or three dimensional, in the case where a friction ridge comparison cannot be conducted.

Multistep impression The impression of the foot left inside footwear created overtime through repeated steps of the foot, creating indentations, and darkened sweat stains of the wearer's foot.

Single step impression The impression of the foot left by a single step of the foot either two or three dimensional.

Sock foot impression The impression of a foot clad in a sock.

Weight-bearing impression The impression the foot left on a surface when weight is borne on the foot.

History

Barefoot evidence was introduced in courts as early as 1888 in France, when a criminal by the name of LeDru was identified through the analysis of footprints. Early cases were based simply on the assumption of the uniqueness of barefoot impressions; however, it is only in the past few decades that research has been conducted, published, and peer reviewed, which supports this earlier assumption.

In 1909, G.W. Gayer commented that the footprint features have as much character as the features of the face and that it was obvious that every individual footprint must have a distinct individuality.

Some of the earliest research that sought to determine if the human footprint is highly individual was conducted in India. One such study, in 1980, involved a collection of 725 individuals' footprints and found that a comparison of the foot impressions indicated that combined probabilities could prove reasonably reliable circumstantial evidence to link a criminal with crime.

Research is often case inspired; for instance, in 1981 in New Jersey, USA a case involved a partial bloody socked foot impression at a homicide scene, which was compared to the foot impressions of two suspects. One suspect's foot impressions were eliminated as having created the impression at the crime scene while the other suspect's foot impressions were found to be such that the expert declared a high probability that the impression was hers. Researchers, in this case, collected 100 person's footprints and compared them to the suspect's known foot impressions. They compared the suspect's impressions with the 100 research subjects foot impressions and concluded that the more unique the individual features of a particular print, the smaller will be the probability that another individual could have left a sufficiently similar print to allow nonexclusion of that person. In addition, they conducted an independent test of this theory where a series of partial prints taken from research volunteers were selected for

testing. Identifiers were removed and compared to a random sample of 50 barefoot. The results demonstrated the accuracy of nonexclusion method applied to partial prints and complete prints.

Another research project conducted by the FBI started in 1986 included 500 adults' footprints in order to provide more information about the degree of individuality expressed in the impression left by the human foot. This study too found that basic size and shape features varied considerably among the foot prints collected reflecting a highly significant degree of individuality. Blind searches of impressions that were either in or not in the database were made as a measure of determining how these factors could be used to discriminate footprint impressions from one another, and it was determined that only five or fewer of the more general characteristics were necessary to either identify or discriminate these footprints from all others in the study.

In 1989, the largest scale research project to date was initiated by the Royal Canadian Mounted Police, which sought to build on the earlier research conducted, taking into account intraindividual differences of persons' footprints contrasted against interpersonal differences between individuals encompassing a cross section of male/female and Caucasian/non-Caucasian (self-declared) sampling.

The initial pilot project included 960 people, with a repetitive sample of 20 persons who provided footprint impressions three times a day, over 3 days during a week period to provide the intrapersonal differences. Subsequently, a larger study was undertaken, involving 5755 people with a repetition sample of 134 people.

In this study, foot impressions of monozygotic twins (Figure 1) and numerous contributors who donated their foot impressions to the research database multiple times over the span of 5–15 years demonstrated both the high degree of variability and the persistency of the weight-bearing impressions of the foot. The friction ridge skin of the plantar surface of the foot has the same individualizing ability based on its uniqueness

Figure 1 Inked barefoot impressions of the left feet of a pair of monozygotic twins. This shows the differences between the placement of the toes, the presence of toe stems, and differences in the arches between the two persons' foot impressions, demonstrating the high degree of variability.

even in a small area, as well as its persistence over the life span of the individual, as the friction ridges on the palmar surfaces. In the case of foot morphology, however, the morphological weight-bearing impressions left by the foot are examined, where the friction ridges are not visible or do not display sufficient clarity to conduct a friction ridge comparison. The repeated donors of weight-bearing impressions over the span of a number of years have shown that the morphological shape of the weight-bearing impressions of the foot are persistent over time and unique to the individual (Figure 2).

Foot impressions were measured and scanned, and the foot impressions were searched against all other impressions in the data base. At first, exact measurements were used to search the database to see whether any two barefoot impressions matched, and it quickly became apparent that after only three to five measurements, every foot was found to be new to the database, even those from repeat donors. This demonstrated that barefoot impressions from the same donor could not be repeated exactly. As in any impression making process, it is highly unlikely that two impressions of the same items will be identical; therefore, even barefoot impressions from the same donor show small, but measurable, differences. As new foot impressions were entered in to the database, they were automatically measured by the program and searched against the existing database as it was being entered, initially using a 5 mm window on each measurement to increase the chances of finding two feet that were similar. This was successful in finding apparent matches by the computer search; however, every pair selected was examined and confirmed to be two impressions from the same volunteer. Only when the search window

Figure 2 Inked right barefoot impressions of the same person taken 11 years apart. Demonstrates persistence of the foot morphology of the weight-bearing impression over time.

was widened to 15 mm impressions from two different individuals come up as a match based on the measurements. In each case, when an examination by a trained forensic specialist was conducted, it was confirmed that the impressions were in fact easily distinguishable as being from different people.

A statistical analysis has been carried out using only 19 of the possible 119 measurements of 5755 pairs of inked barefoot impressions, which resulted in the probability of a random match of 1 in 1.27 billion, indicating the high degree of variability of barefoot impressions. It is recognized, however, by forensic specialists conducting examinations, that the research completed utilized ideal footprint impressions, which are whole, clear, distinct barefoot walking impressions on paper by a cooperative donor. Poor quality samples, or ones that were smeared or unclear, were not utilized in the research. In actual case work, the impressions collected at a crime scene will likely not meet these specific criteria, and the crime scene examiner does not have the option of choosing only the pristine impressions. Consequently, barefoot morphology examiners use a much more conservative approach in expressing the level of certainty of their conclusions and do not use a numerical statistical probability.

Crime Scene Evidence Collection

The forensic investigator who attends the scene of a crime is the first person who will determine whether there is

Figure 3 Examination quality photograph of a barefoot crime scene impression enhanced chemically with Amido Black. Photo taken by Cst J. Jackson.

barefoot impression evidence present and collect it for later examination by a barefoot morphology examiner. It is recommended that all impressions visible be photographed before enhancement and post enhancement using proper forensic photography principles and protocols. Examination of quality photographs of the barefoot impression evidence must be taken using a scale in the photographs with the film plane or charge-coupled device (CCD) of the camera parallel to the impression being photographed (Figure 3).

Enhancement techniques may be necessary, including but not limited to the use of forensic lighting techniques and chemical enhancement techniques. Impressions may need to be lifted using electrostatic lifting devices, gelatin lifting if dust impressions are present, or regular footwear impression lifting techniques may be necessary depending on the development technique utilized. Whenever possible, if the case warrants it, cutouts of the impressions should be considered as well. Items are marked as exhibits, and continuity should be strictly maintained.

Collection of Exemplars from a Person of Interest

The collection of known impressions from individuals is the next step in the process.

Every effort should be taken by the investigators collecting the exemplars to adhere to the standard operating procedures or guidelines available and appropriate care is taken to ensure that the necessary and best possible exemplars are collected. The list of specific types of exemplars will be based on the crime scene impressions, and whether they are two or three dimensional.

When footwear is the questioned/unknown exhibit requiring foot morphology analysis and comparison, in addition to the other exemplars previously described, the footwear worn by the suspect should be seized as well, either pursuant to arrest or by Judicial warrant. If possible, other footwear known to be worn by the suspect should be seized.

Photographs should be taken of the subject's feet with scale, including the soles, tops of the toes, sides of the feet, and heels. Photography is normally followed by the taking of three-dimensional weight-bearing impressions of the soles of the feet, using a foam material such as Biofoam or Foam Art, which is used by chiropodists (podiatrists). The impressions are taken by having the subject place weight on the foot into the foam material. An actual-sized representation of the bottom of the subject's feet will later be prepared by pouring dental stone into the foam impressions, making a positive cast of the individual's foot (Figure 4).

Actual-sized casts are made of the tops of the toes using a silicone-casting material such as Ruthinium Labor Mass, a silicone material commonly used by dentists. The material is mixed with catalyst, which is placed over the subject's toes, and allowed to harden before being removed. This too will later be cast with dental stone by the foot morphology examiner, making a positive cast of the subject's toes (Figure 5).

Next, inked impressions should be taken of the subject's feet. It is important that both standing and walking impressions, with and without socks, are taken. The inked impressions are taken from an individual on a piece of paper approximately 5–6 m long and approximately 1 m wide. An inking pad is made using an acetate covered piece of cardboard large enough for a person to stand on. Fingerprint ink is spread over the acetate using an ink roller to smooth out the ink. The individual stands barefoot on the inked pad, rocking back and forth to ensure that the feet are inked properly. He/she then walks the length of the paper to the right side and walks back on the left side of the paper. Sufficient ink must be applied to ensure that the subject deposits a diminishing series of foot impressions of each foot (8–12 impressions of each foot). Attention should be paid to the individual's feet to ensure that the person is walking normally. Ink is reapplied, and static (standing) impressions are taken barefoot. Next close fitting, thin socks are supplied to the subject and the walking and static impressions are taken in the same manner as the barefoot impressions described previously (Figure 6).

If the specifics of the creation of the crime scene impression are known, for example, through surveillance video footage, it is a possible attempt to take additional exemplars recreating unusual barefoot impressions. An example of this would be if there existed evidence that the crime scene impression was produced while running, or traveling up or down a set of stairs. Any additional exemplars that might be considered should only be done after consultation with the barefoot morphology examiner, with the authority of the court, and after taking the standard format exemplars already described.

Figure 4 Photograph of a three-dimensional dental stone cast created from an impression of a subject's foot in Biofoam.

Methodology for Examination of Foot Morphology Cases

When a forensic specialist receives a case for examination, strict evidence continuity must be maintained for court purposes. When exhibits are received, they should be initialed and dated by the examiner to maintain the continuity. The examination is conducted, following accepted forensic methodology, known as ACE-V. The acronym ACE-V is commonly used to describe the process involving analysis, comparison, evaluation, and verification. The crime scene impressions, or unknowns are analyzed first, before analyzing the known exemplars, and the comparison is conducted from unknown to known. An evaluation of the similarities and differences is undertaken, after which the examiner reaches a conclusion of elimination, inclusion as the possible source of the crime scene impressions, or, in rare circumstances, individualization.

Analysis of Crime Scene Impressions

Crime scene impressions are invariably not pristine impressions. They may be partial impressions, multitap, distorted

Figure 5 A three-dimensional dental stone cast created from a Ruthinium Labor Mass Silicone cast of the top of a subject's toes.

Figure 6 Inked barefoot walking impressions and inked socked foot walking impressions taken for foot morphology comparison purposes.

impressions, or stepped on by other feet/footwear. During the analysis phase, the examiner must attempt to determine what variables existed in the depositing of the crime scene impressions so that they can be taken into consideration. For example, the impression could be wet or dry in origin. A wet origin blood impression on a tile surface floor has different inherent traits than a dry origin dust impression on a fabric surface. An impression may have been deposited in a normal walking stride, or it may have been deposited with significant movement during a quick turn during a running stride. All factors concerning the deposition of the impression must be analyzed by the examiner.

Factors that affect the impression making process are analyzed by the examiner. Areas to consider, when possible to determine, are the surface on which the impression is deposited, the medium of which it is made, deposition pressure, movement and pressure distortion, the development medium, and any inherent signatures of that process. Although all these factors are analyzed and considered, the primary limiting factor of the weight-bearing foot impression is the clarity of detail visible.

All crime scene impressions supplied to the examiner are enlarged to actual size and analyzed. If necessary, digital enhancements will be used, adhering to established protocols and making a record of all adjustments made, on a copy of the original image. The actual-sized photograph is overlaid with acetate and the examiner will trace all visible detail and make other bench notes concerning their analysis of each crime scene impression.

When the unknown crime scene impression is inside footwear, the shoes will be photographed, paying close attention to the location of general and specific wear on the out sole of the footwear. The wear on the outsole of shoes and the weight-bearing impressions inside footwear are multistep impressions, created by stepping thousands of times per day, leaving wear on the outsole and sweat stains, wear marks, holes, and indentations on the insoles. The degree of wear and visibility of the damage is dependant on multiple factors of the footwear itself, and the wearer of the shoes. The top portion will be cut from the shoe and any foreign material present (hair, fibers, soil, dirt, etc.) will be collected from inside the footwear and provided to the investigator who can then submit this trace evidence for analysis to the appropriate section of a forensic laboratory. An examination of the inside upper and insole of the shoe will be conducted, and all visible damage, wear marks, and stains that may have been caused by the feet will be photographed (Figures 7 and 8).

To date, the best enhancement techniques have been found to be in the use of specialized forensic light sources. The light source that provides optimum results will be used to photographically record the impressions within the footwear. The photographs taken with the scale of damage and weight-bearing impressions inside the footwear are enhanced, enlarged to actual size, and analyzed similar to the process used for two-dimensional impressions described above. Analyses of the impressions inside footwear are also limited by the clarity of the weight-bearing impressions and stains and damage visible within them.

Analysis of the Known Exemplars

Persons of interest to the investigation may have a vested interest and may attempt to provide inaccurate representations of their weight-bearing foot impressions. The subject may deliberately attempt to disguise their impressions by scrunching their feet, walking in a manner that is not normal for them, or twisting their feet while walking. It is important to visually observe, and if possible, have video recording of the person of interest walking before being advised of the reason of the collection of the exemplars, as well as during the impression taking procedure. This assists the barefoot morphology

Figure 7 The weight-bearing impression visible on the insole of a shoe cut apart for foot morphology comparison.

examiner by allowing them to view the video, and determine if attempts were made to deliberately change their weight-bearing impressions. The examiner will view and enlarge if necessary the photographs taken of the subject's feet for visualization and recording of any peculiarities or damage to the feet that may have been caused by the footwear.

The three-dimensional molds that were made of the subjects' feet will be cast with dental stone, to create life-sized molds of the subjects feet. The inked impressions are examined to discern if there are any discrepancies that might be present between the standing and walking impressions. When examining the walking impressions, all left-foot impressions should have similar shapes and size, as should all right-foot impressions. Representative samples are cut out from the roll of walking impressions. All material-, such as other footwear, molded impressions and photographs obtained of the feet of the subject should be examined.

Figure 8 The inside upper portion of a shoe that has been cut apart, showing the marks and damage left by the tops and ends of the toes inside the shoe.

Comparison

It is preferable, but not absolutely necessary, to compare the like impressions, that is, comparing two-dimensional impressions with two-dimensional impressions and three-dimensional impressions with three-dimensional impressions. Actual-sized photographs that had been prepared, along with traced overlays created by the examiner of both the known and the exemplar impressions are used. Traced overlays are an invaluable investigative tool when comparing the location and shape of various characteristics or areas of the foot.

The comparison of barefoot impressions is treated as any other physical match and incorporates the same methodologies and scientific approaches. Clarity is one of the most important elements. All characteristics in a physical match must be analyzed, compared, and evaluated before a conclusion is reached.

Examiners work from unknown to known, with the first goal being to attempt to eliminate the person as the source of the impression if possible. If elimination of the person is not possible, then the comparison process continues.

The first step in the comparison process is to examine what may be described as class characteristics. Class characteristics are those that are common to more than one foot; for example, the overall size of the foot, the fact that the correct number of toes are present, and the width of the ball and heel of the foot. The finer details of the foot impressions are then compared. For example, the examiner should look at the shape and placement of each toe, the spatial relationship of the toes to one another, the distance from the ridge that separates the ball of the foot from the toe pads, the contour of that ridge, the contour of the ball of the foot, and the shape and length of the arch, shape and size of the heel area.

While each feature individually may not be unique, the features in combination can make the impressions of different persons distinguishable. An examiner must also evaluate any temporary changes in characteristics that may have been caused by injury to the foot and that are not part of the permanent foot

morphology. Accidental characteristics such as a nail through the sole of the shoe, which has damaged the foot, or visible permanent features such as creases can be used in conjunction with foot morphology to individualize the bare foot.

When comparing impressions inside a shoe, the same process is used. All detail present in the shoe is examined in a similar manner, and all known exemplars available are used in the comparison process. If no shoes known to be worn by the subject are available for comparison purposes, comparisons can be conducted with the use of inked barefoot impressions to the weight-bearing impressions inside of unknown shoes. One researcher who specifically explored this type of comparison found that inked impressions as known exemplars can be used though caution should be employed.

Evaluation

The examiner reaches a conclusion based on the evaluation of the comparison process and the similarities and differences noted during comparison. For example, there may be differences noted, which are explainable from the factors or distortions observed during the analysis of the unknown impressions or known impressions. The examiner articulates the process used and, ultimately, expresses an opinion. Once their opinion has been reached, the examiner prepares a written report and submits this with all of the materials used to a second qualified examiner for independent analysis, and if they agree with the conclusion stated, verify the original examiner's opinion.

The opinion or conclusion reached can range from the following:

1. A lack of sufficient detail for a meaningful comparison, whereby in the opinion of the examiner, there is insufficient detail in the unknown impression to conduct a meaningful comparison/evaluation.
2. Elimination/exclusion, whereby in the opinion of the examiner, there are sufficient differences, without explanation, such that the examiner would eliminate the suspect as a source of the unknown impressions.
3. Inclusion of the source of the known exemplars as being the possible donor of the unknown foot impressions, whereby in the examiners opinion, there is an agreement of morphology of the weight-bearing impression, such that they could have made the unknown impressions.
4. Individualization of the unknown impression as having originating from the subject who provided the known exemplars, whereby in the examiners opinion, there is an agreement of the morphology of the weight-bearing impression and the presence of additional accidental characteristics (e.g., flexion creases, scars) that are visible and also found to be in agreement between the unknown and known impressions.

Verification

Once the examiner has conducted a full examination, involving analysis, comparison, and evaluation, a full report is prepared, and the case file and all materials used are submitted to a second qualified examiner for a peer review of the process

and conclusions reached. The second examiner's role is to repeat the process used, verify the methodology that was followed, and reach their own opinion, which if in agreement, verifies the opinion of the first examiner.

Barefoot morphology comparison should only be undertaken by properly trained forensic specialists, using established comparison methodologies of forensic physical evidence comparison, which may provide circumstantial evidence to assist in the exclusion or inclusion of a person as the potential source of the crime scene barefoot impression, providing additional information to the courts if required.

The Friction Ridge Skin of the Feet

D Johnson, Las Vegas Metropolitan Police Department, Las Vegas, NV, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Friction ridge skin has been used for over a hundred years for personal identification and for the identification of latent prints left at crime scenes. A majority of the focus of the study of friction ridge skin has been on the fingers and palms. The same type of friction ridge skin that covers the surface of the hand also covers the soles of the feet. It is both persistent and unique through the same mechanisms as that of the friction ridge skin of the hands. However, the general ridge flow and pattern types found on the feet can be very different. The notable differences in physiology and embryology of the foot and volar pad size, shape, and placement on the foot lead to some stark differences in the ridge flow and crease patterns on the plantar surface.

History

The use of friction ridge footprint evidence in US courts dates back to 1938 with the case of the Commonwealth versus Bartolini. Bartolini had been identified as the person who left a bare footprint on the floor of a homicide scene. The defense challenged the use of footprints citing that the expert in the case may have been familiar with fingerprints but was not qualified to give testimony on footprints. The court affirmed the conviction of Bartolini stating that the expert in the case had sufficient knowledge of footprints and that there was 'ample evidence that footprints, like fingerprints, remain constant throughout life and furnish and adequate and reliable means of identification.'

The first use of toe prints in the United Kingdom dates back to 1952. In *HMA versus William Gourley*, a bakery was broken into and several footwear impressions and two impressions of the left foot were recovered. The lock on the safe had been blown and a pry bar was used to open the safe. The two impressions recovered from the safe contained sufficient detail of what appeared to be the left big toe. Gourley was arrested, exemplars of his feet and toe prints were taken, and he was identified to the toe print that was recovered from the safe. The defense challenged the identification saying that the witness did not have enough experience to testify on toe prints. This was the first case in the United Kingdom where a toe print was the sole evidence against the suspect. The jury found Gourley guilty within 15 min and he was sentenced to 3 years in prison.

Later that year, in December 1952, in the United Kingdom, there was a break-in at an Aberdeen warehouse. The scene was processed for fingerprints but only glove marks and the impressions of stockinged feet were recovered. The suspect had taken care not to leave footwear impressions and fingerprints by removing his shoes and wearing gloves. The stockings appeared to have holes in them allowing the transfer of some of the friction ridge detail from the feet to be recovered. James Walker Adams was identified as a suspect because he had used

a similar MO in previous break-ins and had been identified through the use of fingerprint and footwear on previous occasions. Adams was identified as having left three impressions. The same defense counsel that represented Gourley was used in *HMA versus James Walker Adams*, and the defense questioning of the expert witness followed much the same line. The jury found Adams guilty in only 5 min and he was sentenced to a year of jail time.

Recent court challenges using the Daubert or Frye standard in the United States have focused their attacks on the friction ridges of the fingers and the palm. Subsequently, research conducted to answer those Daubert and Frye challenges has only been on the fingers and the palms. While the courts currently recognize the acceptance of friction ridge identification in general, research could be conducted to strengthen this area of the science.

Embryology and Development of the Friction Ridges of the Foot

The development of the foot, the friction ridges, and the creases takes place over an estimated gestational age of 6–18 weeks. The sequence of events in the foot is very similar to that of the palms and fingers; however, the timing of events in the feet is delayed by about a week to 2 weeks. Several different factors help determine the overall ridge flow and pattern types present in the toes and feet. The shape and growth stresses of the foot and the genetic, environmental, and random factors cause the individual ridge and crease paths to be random. To understand this critical time in friction ridge development is to understand the resulting friction ridge patterns that can be seen on the skin.

Between 6 and 13 weeks of gestation, the feet will develop from flat paddlelike structures to something that resembles an infant's foot. Although at 6 weeks there are interdigital notches in the hands, they do not form in the feet till about 7 weeks. At about 8 weeks, the toe rays have formed and the heel is raised. At 9 weeks of gestation, the thenar, hypothenar, and interdigital pads are formed and one of the primary creases, the metatarsophalangeal creases, is visible. At 11 weeks of gestation, the pads have begun to regress, and by 13 weeks, the pad regression is all but complete on both the hands and the feet. Most of the primary creases have formed, but there is still some development of creases up until 20 weeks of gestation. While all fetuses will undergo the sequence of events described above, there will be variation between the size, shape, and timing of the regression of the volar pads. All these factors help contribute to the unique friction ridge pattern that is formed on the feet (**Figure 1**).

Development of the Arch

Children are born with flat feet and the foot will continue to grow and develop as they age. It is not until 2–3 years of age

that the arch begins to develop. The development of the arch can cause the formation of many new secondary creases in the tibial thenar. These creases are the result of the new concave shape of the foot in this area. In cases of flat-footedness, these creases are absent.

Recording Known Impressions of the Foot

One method that is used to obtain inked prints of the feet is to apply ink to the soles of the feet and have the individual walk across a large sheet of paper. This will typically record the weight-bearing areas of the foot as well as the friction ridge detail. This can make these types of known prints useful for not only latent print comparison but also for the comparison of the shape of barefoot impressions. The disadvantage of this method is that it will not give the friction ridge examiner a complete recording of the friction ridge detail of the feet. Most of the surface of the toes, the arch, and the outer portions of the hypothenar and the heel will not be recorded.

Similar to the method used for rolling palm prints, a large cylinder approximately 5" in diameter and a legal size piece of

paper (8.5" by 14") can be used to roll an impression of the feet. Just as in the procedure for palm prints, the foot should be rolled across the surface of the cylinder in one continuous motion, from the heel to the toes.

Alternatively, a light coating of powder can be applied to the surface of the feet and a white adhesive lifter (e.g., Quik-print, Handiprint). This technique has the advantage of being able to wrap the lifter around the surface of the foot, thereby recovering a more complete recording of the friction ridge detail.

When taking exemplars of infants, it is suggested that a ceramic inkpads and a rigid surface such as a clipboard will produce the most reliable images. Several steps are necessary to capture infant footprints. The foot should be washed to remove any biological fluid and thoroughly dried. Using an inkpads, a light coating of ink should be applied and using very light pressure pressed against a rigid surface.

Ridge Flow of the Feet

Latent prints from the feet are occasionally recovered from the crime scene. When the impression is of sufficient quality and size, it is very easy to determine the source as having come from a foot. However, when the latent print is of a reduced size and quality, it can be difficult to determine that the source is a foot. These impressions can often be confused as having come from a palm (Figure 2).

The same principles of identification that are employed in fingerprint and palm print identification should be used in footprint identification. As footprints and toe prints are not routinely compared by latent print examiners, care should be employed. The question of how much is enough, still an unanswered question in the areas of fingerprint and palm print identification, has received even less attention in the footprint identifications.

Figure 1 Kimura and Kitagawa.

Figure 2 Footprint developed with rhodamine 6G.

Figure 3 Holt, Genetics of Dermal Ridges. Areas of the foot: hallucal (I interdigital and thenar distal); II, III, and IV interdigital; hypothenar distal; hypothenar proximal; thenar proximal; and calcar.

The foot can be divided into eight areas that can aid in classification. Distal and proximal retain their meaning; however, the terms ulnar and radial should be replaced with tibular and fibular, respectively, to reflect the bones of the calf rather than the bones of the forearm (Figure 3).

Hallucal (Distal Thenar and First Interdigital Area)

This is the major pattern area of the foot. This is the combination of the first interdigital area and the distal thenar. This is the most patterned area of the foot and can contain a wide variation of loops, whorls, and arches. Understanding the types and shapes in this area can greatly aid in identifying latent prints, as having come from the foot as the hallucal is one of the more common areas that will leave a latent print (Figure 4).

In a small collection of 84 feet, there were only two distal arches.

II, III, and IV Interdigital Areas

The remaining interdigital area can be divided into three separate pattern areas. The five triradii that are typically found in the interdigital area can be used to delineate the different pattern areas as shown in Figure 5. These triradii bear the same designation as they would in the palm, with the

Interdigital area	Whorl (%)	Loop, distal (%)	Loop, proximal (%)	Open (%)
II	0.15	6.6	2.05	91.2
III	0.65	57.7	0.2	41.55
IV	0.0 ^a	8.05	0.1	91.9

Based on data from Takeya 1933, 1000 right and 1000 left feet.

^aThere were no occurrences of a whorl in the IV interdigital area.

exception of 'E' under the great toe, which has no corresponding delta in the palm.

Distal/Proximal Hypothenar

When examining the weight-bearing portion of the distal and proximal hypothenar, it was found that most feet exhibited horizontal flowing ridges. When the fully rolled impression was recorded, a loop in the distal portion was found with

	Open field (%)	Vestige (%)	Loop (%)
Distal hypothenar	27.0	37.1	35.9
Proximal hypothenar	81.7	15.3	3.1

Based on data from Takeya 1933, 1000 right and 1000 left feet.

Figure 4 Picture of whorl, loop, open, and arch. Whorls, 30.7%; distal loops, 48.5%; tibial loops, 7.3%; and open, 12.2% (Based on data from Takeya 1933, 1000 right and 1000 left feet).

Figure 5 Interdigital area of the left foot.

increasing frequency. While different variants of pattern types are possible in this area, they were fairly uncommon with the distal loop near the IV interdigital being the most common pattern.

Tibial Thenar

The tibial thenar area is most typically highly creased and the ridge flow is very similar to the weight-bearing portion of the hypothenar. The most common feature of this area is the straight horizontally flowing ridges with little to no patterning. In the proximal portion of the tibial thenar lies the thenar rudiment. The thenar rudiment is a wedge-shaped ridge flow pattern that is commonly found where the arch of the foot ends

and the heel begins. As this area is not often fully recorded, additional variants of the ridge flow are possible.

Calcar

The calcar or heel area of the foot is predominantly an open field. The calcar area bears patterns in approximately 1.0% of the cases. Some of the subsets of populations surveyed had percentages ranging from 0.7% to 2.2%. It is still fairly clear that any type of pattern in the calcar region is a rare event. There is some evidence to suggest that patterning in the calcar region is genetic and can be shared among siblings and passed down from generation to generation. However, as most recording of the heels are incomplete, the calcar loop may be more common than is currently thought.

Toes

The distribution of pattern types on the fingers is fairly well known and studied. Again, this is an area that has received little attention in the feet. There is very little information that has been published on the toes. The toes provide some difficulties to researchers, and the pattern area is not recorded on typical plain impressions. The big toe is typically flat, but the remaining toes curl under so that only the tips are recorded (**Figure 6**).

The distribution of pattern types on the toes is very different than that of the fingers. Arches are far more common and whorls are less common. The loops, however, only occur about 5% less than they do in the fingers.

Figure 6 Different pattern types of the toes.

Figure 7 Latent lift of the toes and the hallucal area from a safe.

	<i>Arches (%)</i>	<i>Loops (%)</i>	<i>Whorls (%)</i>
European-Americans (Neman)	13	64.4	22.6
Germans (Steffens)	19	59.3	21.7
Chinese (Takeya)	21.8	59.9	20.7
Japanese (Hasebe)	21.8	61	17.2

Toe patterns tend to have smaller ridge counts than the fingers. In a study of twins, it was found that the average ridge count for the fingers was approximately 14.3 and for the toes 10.6 (Figure 7).

Without knowledge of the ridge flow of the feet, this impression may be interpreted as being from the thumb and part of a palm. If the latent print had been identified as having come from the thumb or part of the palm, it would have resulted in the exclusion of the subject in the case.

Creases

The flexion creases of the feet have been used for many years in the identification of the footprints of infants. Owing to the

difficulty of obtaining legible friction ridge impressions from the feet of infants, latent prints examiners have had to rely on the flexion creases to identify the subjects. As early as 1959, the use of flexion creases to identify infants was being used and accepted by the courts. In the case of the People versus Iavaroni – County Court, Brooklyn, NY – an infant found in the possession of Mrs. Iavaroni was identified as Lisa Rose Chioncho. She had been kidnapped from the nursery of St. Peter's Hospital. The hospital had taken impressions of Lisa Rose's footprints at birth, but due to the lack of training of the hospital staff, the impressions did not contain any legible ridge detail. When Lisa Rose was found 9 days after the kidnapping, the examiners in the case, Detectives Mandella and Fusci, were able to identify the girl based on the flexion creases alone.

Formation of the Creases

The formation of most of the primary creases is independent of the movement of the hands and feet. Spontaneous movement does not occur in the hands and feet until 11.5 weeks and some of the major primary creases have already formed by this time. Additionally, there are cases in which the primary creases are absent but the individual still has normal movement. Primary crease formation is more closely related to the volar pads than to the movement of the hand and foot. Secondary creases form after the friction ridge skin, and many continue to form in the feet as a person ages.

Creases in the feet are highly variable. Unlike the consistent pattern of the major primary creases in the palm, the feet show a wide variety of crease patterns both in number and configuration. There are anywhere from 0 to 90 creases in the weight-bearing area of the feet, with an average of 15 creases per foot. If the tibular thenar area (arch) were to be included, the number of creases would be much higher.

It is the combination of the differences in physiology, embryology of the foot and volar pad size, shape, and placement on the foot that leads to some stark differences between the ridge flow and crease patterns on the plantar surface and that of the fingers and palms. Familiarity with the different ridge flow and crease patterns of the feet will help friction ridge examiners identify possible foot impressions and avoid erroneous exclusions.

Palm Prints

A Maceo, M Carter, and B Stromback, Las Vegas Metropolitan Police Department Forensic Laboratory, Las Vegas, NV, USA

© 2013 Elsevier Ltd. All rights reserved.

The friction ridges on the palmar surface of the hands develop in utero during the first and second trimester. Like fingerprints, the ridge flows and patterns that emerge on the palms are the product of the growth stresses and strains on the surface of the skin at the time of friction ridge development. These growth stresses, and the size and shape of any volar pads (VPs) present, influence the resulting patterns displayed on the palms (Wertheim and Maceo).

The friction ridge skin on the palmar surfaces has been studied for more than a century. In the late 1890s through the early 1900s, Inez Whipple researched the ventral surfaces of various species of monkeys' feet, focusing on the apical pads, ridge patterns, deltas, and other 'epidermal markings,' comparing them to human hands and feet. Harris Wilder, in his *Palm and Sole Studies*, created a system for recording the configurations of various features on the palms and soles into a formula, easily understood and visualized by someone knowing the system. Cummins and Midlo researched pattern frequencies and intensities (number of deltas) in both right and left palms and soles of chimpanzees. Penrose also studied the pattern frequencies of palms and soles, and he and Loesch classified palmar dermatoglyphics, both normal and abnormal. Malhotra et al. researched the methodology for palmar pattern ridge counts, specifically in Indian genetics. Most recently, in 2001, Tietze and Witthuhn published their work on palm patterns, flows, and deltas, including statistical data in left and right palms. Given that the book is written in German, translation and interpretation is limited; however, the charts and graphs and numerous images are most useful.

To further study the distribution of the various patterns on the palms, the authors devised a classification scheme and recorded the various pattern types present in 800 pairs of inked palm prints (left and right). The palm prints were randomly selected from male arrestees in Clark County, Nevada, from the 1990s. The palms were divided into three regions: interdigital, hypothenar, and thenar. **Figure 1** illustrates the different regions of the palm.

Interdigital Region

Deltas

The interdigital region is the most complex area of the palm. In this study, the interdigital region contained anywhere from three to seven deltas. These deltas often existed in various combinations with tented arches, loops, columns, or whorls in the interdigital region. Seven possible delta positions were documented. Four of the delta positions were situated at or near the base of each finger (finger deltas) and were labeled Index (I), Middle (M), Ring (R), and Little (L). The remaining three delta positions occurred between the fingers and were labeled Index/Middle (I/M), Middle/Ring (M/R), and Ring/

Little (R/L). Occasionally, more than one delta was located in a position (e.g., two deltas under the ring finger). **Table 1** shows the number of palms with the corresponding number of deltas from the 800 left and right palms. The most common number of interdigital deltas in the left and right hands was four.

The position of each delta and the number of deltas in each position were also recorded. **Table 2** shows the number of palms that contained 0, 1, or 2 deltas in each delta position in the interdigital region. As shown in **Table 2**, the overwhelming majority of palms had a delta associated with each finger.

It was very common for the palms to have only the four finger deltas: 553 of the 586 left palms and 591 of the 605 right palms with four interdigital deltas had only the four finger deltas (I, M, R, and L). **Figure 2** is a right palm interdigital region displaying the four finger deltas.

In palms containing only three interdigital deltas, the most common configuration was a delta under the index, middle, and little finger each (the ring finger delta was absent): 31 of 32 left palms and 19 of 19 right palms with three interdigital deltas were missing the ring finger delta. **Figure 3** shows the interdigital region below the right ring finger. In this palm, the ring finger delta is absent.

Interdigital regions with four or more deltas often contained at least one pattern area in the interdigital region. The more patterns present in the interdigital region, generally the higher the number of deltas present. **Figure 4** is a right palm interdigital region displaying six deltas associated with three interdigital loop patterns. In this study, 13 left palms (1.6%) and 18 right palms (2.2%) presented this configuration of six deltas and three loops.

Patterns

The position and types of patterns in the interdigital region were also documented. These patterns included tented arches, loops, columns, and whorls. **Figure 5** illustrates the different patterns. Designation as tented arches, loops, and whorls followed basic fingerprint classification rules. In the interdigital region, however, a tented arch was a ridge flow over an interdigital delta that formed a loop-like pattern (**Figure 5(a)** and **5(b)**). Columns are a series of three or more ending ridges flanked on one or both sides by a delta (**Figure 5(d)**).

The interdigital region was divided into VP regions II, III, and IV as depicted in **Figure 6**. The VP II region is between the index and middle fingers. The VP III region is between the middle and ring fingers. The VP IV region is between the ring and little fingers.

The patterns present in each VP position were recorded for the 800 left and right palms. Only 40 of the 800 (5%) left palms and 29 of the 800 (3.6%) right palms displayed no patterns in the interdigital region. **Table 3** indicates the number of palms with the various patterns in the VP II position,

including the number of palms with tented arches (TA) over the middle finger delta. [Table 4](#) indicates the number of palms with the various patterns in the VP III position, including the number of palms with tented arches over the ring finger delta. [Table 5](#) indicates the number of palms with the various patterns in the VP IV position, including the number of palms with tented arches over the little finger delta. In the VP IV position, there could be a single loop or two loops, which is the reason [Table 5](#) has '1 Loop' and '2 Loops' indicated.

Loops and columns were more prevalent on the right hand (versus the left hand) in the VP II position. This naturally correlates with the higher occurrence of I/M deltas in right palms. The right palms had an equal occurrence of loops in

the VP III and IV positions, while left palms had the highest occurrence of loops in the VP IV position. [Figure 7](#) illustrates a rare and complex VP IV position in a left palm. This palm has a column (A) and two loops (B and C) in the VP IV position.

Loops are the most common pattern in the interdigital region of palms. [Tables 6](#) and [7](#) demonstrate the number of left and right palms containing specific configurations of loops in the various VP positions. For example, there were 111 left palms (14%) with a loop in the VP III position only. There were 13 left palms (1.6%) with a loop in all three VP positions. These tables only refer to loops; other patterns may be present in the VP regions.

Hypothenar

The hypothenar region also contained a variety of patterns. Like fingers, the loops found in the palms flow in a certain direction. For the purposes of this study, the direction the top of the loop was pointing to is indicated (this is reverse from fingerprint classification). For instance, a loop pointing toward the outer edge of the palm is called an 'ulnar loop.' A loop pointing toward the center of the palm is called a 'radial loop,' and a loop pointing toward the base of the palm is called a 'proximal loop.' The ulnar loops are further described by the origin of the ridge flow. If the ridges flow into an ulnar loop pattern from the top of the palm, it is called an 'ulnar loop – top.' If the ridges flow into an ulnar loop pattern from the bottom of the palm, it is called an 'ulnar loop – base.' [Figure 8](#) illustrates two right hand hypothenars. One hypothenar has an 'ulnar loop – top' (A) and a radial loop (B). The other hypothenar has an 'ulnar loop – base' (C). The pattern counts for ulnar loops may be artificially low due to the manner in which the palms were recorded. Sometimes ulnar loops are located far out on the edge of the palm and are not displayed during the recording process; for this reason, the data should be viewed with caution.

[Figure 9](#) illustrates the patterns classified as proximal loop, arch, and proximal loop/arch combination. The proximal loop in the proximal loop/arch classification approaches the radial loop classification; however, it is distinguished by the distinct arch pattern.

[Figure 10](#) illustrates the tented arch patterns noted in the hypothenar region. The tented arches can point in the proximal direction (a) or the ulnar direction (b).

Figure 1 Three palmar regions: interdigital, hypothenar, and thenar.

Table 1 Number of deltas in the interdigital region ($n=800$ for left and right palms each)

Number of deltas	Left palm	Right palm
3	32 (4.0%)	19 (2.4%)
4	586 (73%)	605 (76%)
5	154 (19%)	137 (17%)
6	28 (3.5%)	37 (4.6%)
7	0	2 (0.25%)

Ring	69 (8.6%)	726 (91%)	5 (0.62%)	39 (4.9%)	755 (94%)	6 (0.75%)
R/L	696 (87%)	94 (12%)	10 (1.2%)	661 (83%)	132 (16%)	7 (0.88%)
Little	1 (0.12%)	799 (100%)	0	3 (0.38%)	797 (100%)	0

Figure 2 Right palm interdigital region displaying the index (I), middle (M), ring (R), and little (L) deltas.

Figure 3 Interdigital region below the right ring finger. The ring finger delta is absent.

Figure 4 Right palm interdigital region with six deltas (I, I/M, M, R, R/L, and L) and three loop patterns (highlighted in blue).

Figure 5 Patterns of the interdigital region. (a and b) Tented arch, (c) loop, (d) column, and (e) whorl.

Whorl patterns can also be found in the hypothenar region. **Figure 11** illustrates a double-loop whorl (a) and a plain whorl (b) in the hypothenar.

Columns of ridges can also be present in the hypothenar. These columns can manifest vertically near the carpal delta (delta typically found at the base of the palm that separates the hypothenar and thenar regions) or horizontally throughout the hypothenar. **Figure 12** illustrates a right palm hypothenar with a vertical column (A) and a right palm hypothenar with a horizontal column (B) and an ulnar loop (C).

There was no pattern present in 547 of the 800 (68%) left palm hypothenars and 514 of the 800 (64%) right palm hypothenars. The most common pattern found in the hypothenar was an ulnar loop – top: 156 (20%) left palms and 146 (18%) right palms. The most common pattern combination in the hypothenar was an ulnar loop – top and a radial loop: 9 (1.1 %) left palms and 11 (1.4%) right palms. **Figure 8** (A and B) illustrates this combination.

Table 8 shows the number of palms containing the various hypothenar patterns. Occasionally, two ulnar loops, two radial loops, or two horizontal columns appeared in the hypothenar. A single pattern is designated '(1)' and a double pattern is designated '(2).' One palm could have multiple patterns (e.g., a loop and a horizontal column).

Thenar

The thenar region displays fewer overall patterns than the other regions of the palm. There is, however, one pattern unique to the thenar – the vestige. A vestige is a ridge flow that runs opposite to the main flow of the ridges. A vestige can be small and independent, or it may be quite large and accompanied by loops, columns, or whorls.

The loops and columns were counted together; hence the combined classification of 'loop/column.' A loop/column above the vestige was termed 'proximal loop/column' because the nose of the loop or ending ridges of the column point toward the base of the palm. Occasionally, both a loop and a column appeared above the vestige. The loop/column below the vestige was termed a 'distal loop/column' because the nose of the loop or the ending ridges of the column generally pointed toward the top of the palm.

Figure 13 illustrates right palm thenars with an independent vestige (a and b), a vestige with a narrow proximal loop/column and narrow distal loop/column (c), and a vestige with a wide proximal loop/column and wide distal loop/column (d).

Figure 14 illustrates the whorl (a) and double-loop whorl (b) that can be found accompanying vestiges in the thenar

Figure 6 Volar pad (VP) regions of the right palm interdigital region.

Table 3 Number of palms with the designated patterns present in the VP II position ($n=800$ left and right palms each)

region. The whorl and vestige are also associated with proximal loops/columns above the vestige. Occasionally, a proximal loop/column (c) or a distal loop/column can occur in the thenar independently (no vestige).

Table 9 contains the number of palms displaying a different pattern, and combinations of patterns, found in the thenar region.

Palm prints display four different basic patterns: arches, loops, whorls, and columns. These patterns can occur, independently or in combination, in the interdigital, hypothenar, or thenar regions. The interdigital region displayed the highest frequency of patterns – more than 95% of palms displayed at least one pattern in the interdigital region. Less than 15% of the thenar regions contained a pattern, while approximately 34% of hypothenar regions displayed a pattern.

Latent palm prints are routinely encountered in forensic casework. Through training and experience, analysts develop a sense of the rarity of features, including patterns, in the various regions of the palm. Using data such as these, analysts can better inform their judgments regarding the rarity of these features.

Glossary

Class characteristic A feature that is shared by two or more shoes or tires. The shoe outsole and the physical size features of a shoe outsole are two common manufactured class characteristics. General wear of the outsole or tire tread is also a class characteristic. Agreement of class characteristics alone does not provide a basis for identification; however, it reduces the possible number of shoes or tires that could have made an impression.

Dental stone A gypsum product generally having a pound per square inch (psi) rating of 8000 or higher, commonly used to cast footwear and tire impressions.

Dry-origin impressions Impressions formed under dry conditions such as dry dust and dry residue.

Electrostatic detection apparatus An instrument used primarily to detect indented writing on documents which can also be used to detect footwear and tire tread impressions on paper items.

Individual characteristics Features that have occurred randomly on a footwear outsole. Examples of individual characteristics include cuts, scratches, tears, holes, stone holds, abrasions, and the acquisition of debris from random

events. The position, orientation, size, and shape of individual characteristics contribute to the uniqueness of a shoe outsole or tire tread. Individual characteristics are essential for an identification of a particular shoe or tire as the source of an impression.

Mikrosil™ Silicone casting material used to lift footwear and fingerprint impressions that have been treated with fingerprint powder.

Negative impression An impression that has resulted from the removal of a substance from a substrate by a shoe outsole or tire tread.

Oblique lighting Illumination from a light source that is at a low angle of incidence, or even parallel, to the surface of the item.

Outsole/sole The bottom portion of the shoe that comes into contact with the ground.

Positive impression Deposition of a substance onto a substrate by a shoe outsole or tire tread.

Wet-origin impressions Impressions formed under wet conditions including impressions consisting of residues of blood, grease, mud, and other wet substances.

Introduction

Footwear marks are the result of direct physical contact between an item of footwear (shoe or boot) and a surface. The mark is made either through the transfer of material, such as blood or dust, or by making an impression in a malleable material, such as sand or snow. The quality of a footwear mark is dependent on the amount and clarity of the footwear outsole detail that is present in the impression and recovered for subsequent examination. Methods for detection and recovery include photography, lighting techniques, lifting, casting, and enhancement.

Footwear evidence can provide important crime scene information, including the brand of footwear that produced the impression, movement of individuals within a crime scene, and information regarding the number of individuals present. Examination and comparison of footwear evidence may associate or exclude specific shoes or boots as the source of crime scene marks. It is the role of the forensic footwear examiner to conduct this type of analysis.

Types of Footwear Marks

Footwear marks are also referred to as footwear impressions and shoe prints. These terms are used interchangeably to describe both two-dimensional and three-dimensional impressions of

shoes, boots, and other items of footwear. For simplicity, the general term 'impression' will be used hereafter to refer to all forms of footwear evidence.

Two-dimensional impressions are the result of a transfer of a trace residue between the outsole of a shoe and a receiving surface. A shoe may deposit residue to a relatively clean surface, resulting in a positive impression of the outsole, or a shoe may remove residue from a surface, resulting in a negative impression. There are many types of residues that may be transferred by shoes; the common types are dust, blood, moisture, grease, and oils. Some of these impressions are difficult to detect as they are 'latent' or not readily visible to the naked eye. They also may be transferred to or from a variety of surfaces or substrate types. These surfaces may be porous, such as carpet or paper, or nonporous, such as cement, tile, or wood. Two-dimensional impressions may be classified as either 'wet origin' or 'dry origin' depending upon the amount of moisture involved in their original deposition. The particular combination of deposition material and substrate type determines the method of recovery.

Three-dimensional impressions are made when a shoe presses into any material capable of shape retention such as mud, snow, sand, or soil leaving a depressed mark. This impression may be deep or shallow, and is usually recovered utilizing photography and casting techniques.

A wide variety of factors affect the amount of detail in an impression. For example, the movement of the foot during

deposition, such as twisting or sliding, may prevent a clear replication of the outsole. Some conditions are more conducive for resulting in a clear detailed impression than others. Heavy amounts of blood on an outsole may fill voids, limiting the transfer of design features, while a thin layer of blood may result in an impression with fine and minute detail. Mud with an excess of water or extremely dry sand may collapse in on an impression soon after it is made and impressions in snow may melt before they are detected or recovered. Some substrates, such as untreated wood or gravel, have rough textures that limit the replication of outsole features.

Recovery of Impressions

The potential value of footwear evidence to an investigation relies heavily on successful location of the impressions and proper application of recovery techniques. Footwear evidence most often occurs on floor surfaces, and is potentially damaged if tracked over by other individuals before it is detected and preserved. In order to avoid unintentional destruction of this evidence, the scene should be secured as soon as possible and steps should be taken to preserve and protect footwear evidence at the outset. These methods include the definition of a path of travel through the scene to avoid footwear evidence and protection of impressions from accidental damage and environmental degradation such as melting of snow impressions, blowing wind, or rain. All impressions have potential value; partial or faintly visible impressions are more common and in many cases more detailed than full or readily visible prints, particularly if proper enhancement techniques are used.

Detection

Many impressions are visually obvious at a scene whereas others require methods and techniques to detect. These methods may include the use of oblique light, alternate light sources, powdering and/or lifting techniques, or application of enhancement processes to particular areas of interest. Areas commonly searched are entry/exit points, paths of suspected travel, and items that may have been stepped on, such as tables, countertops, or papers on the floor. Exterior areas should be extended to include potential arrival and departure areas of the scene perimeter.

Photography

Impressions are documented through both general scene and close-up photography. The location of impressions, their context within the scene, and relative location to other items of evidence are examples of the types of information recorded by general scene photography.

Examination quality photographs of footwear impressions are composed specifically to be used for examination and comparison purposes. These photographs are taken with a camera capable of capturing sufficient detail (e.g., a digital camera with a resolution of 10–12 megapixels). The camera should have interchangeable lenses and be capable of manual focus. A tripod is used to place and hold the camera directly over the impression, with the surface of the lens parallel to the

Figure 1 Demonstration of the proper use of a tripod and camera position for examination quality photography of footwear evidence. The camera is manually focused for maximum clarity of the bottom of the impression. A proper scale is next to, and in the same plane as, the impression.

impression (Figure 1). A removable flash or flash with a long extension cord is used to provide oblique light during exposure (Figure 2). Each examination quality photograph should include a scale. Recommended qualities for the scale include fine scale divisions, flat and rigid construction, nonreflective surface, and the ability to be clearly photographed in a variety of lighting conditions. Commonly, forensic scales have dark and light sides for this reason. Scales are placed next to two-dimensional impressions, and at the same level at the bottom of three-dimensional impressions. Placement of the scale ensures accurate enlargement to natural size for comparison. For three-dimensional impressions, the scale should be placed on the same level as the bottom of the impression. Identifiers, such as impression number, photographer, date, and case number should be included in each photograph.

Photographs are taken using lighting techniques that provide the maximum contrast and recording of detail. Some impressions, such as those in dust, light-colored sand, or snow are difficult to photograph due to the lack of contrast present. For impressions such as these, it is important to employ a variety of lighting techniques to capture sufficient detail. In some cases, paint or snow print wax may be used to increase contrast of the impression detail for photography. It is important to photograph impressions before and after any collection or enhancement technique is applied. Examination quality photographs are composed to fill the frame with the impression and the scale. For three-dimensional impressions, sufficient depth of field and aperture priority or full manual mode should be used to keep all depths of impression detail in the range of focus.

Newer technologies including short-wave infrared, and both laser and high-intensity light scanning methods are currently being researched and may someday provide a viable alternative to current photographic techniques.

Figure 2 The use of oblique light is a technique used to increase the contrast of detail for detection and photography. The impression should be photographed with oblique light originating from at least three directions to capture detail occurring in shadows.

Collect the Original Impression

Whenever possible, the original impression should be recovered for examination, provided transfer can occur without damage to the impression. These impressions should be photographed at the scene and packaged to preserve the impression. Items such as impressions on pieces of paper or broken glass are examples of items that might be collected. In some cases, removal of sections of flooring or carpet to allow for transfer of bloody or other impressions to the laboratory for more extensive enhancement methods and examination is recommended. The determination to collect larger items, or items that require the removal of wall or flooring material, is made on an individual case basis.

Lifting

Lifting techniques transfer residue material to another surface to collect the impression and to provide increased visualization of the impression detail. Lifting techniques may also be applied as a searching tool.

Electrostatic lifters use a high-voltage electricity source to create static electricity between a collection film and the impression material. Utilized for dry-origin impressions in dust, the black surface of the film provides increased contrast, allowing for improved visualization of the impression detail. This technique can be used on a wide variety of surfaces and may be used to search large areas for latent dust footwear impressions. Any impressions which are not successfully lifted are not damaged by this process, which allows for subsequent application

Figure 3 Dental stone, mixed with water in a plastic bag, is carefully poured onto a three-dimensional footwear impression in sand to cast the impression.

of other enhancement techniques. Electrostatic lifts must be handled with care, as the impression on the film is easily damaged.

Gelatin lifters are constructed as a gelatin coating on the surface of a pliable backing material. The gelatin is covered with a clear plastic sheet that is removed before lifting an impression. They are used to recover dry-origin and some wet-origin impressions. Lifts may be photographed using special lighting techniques or may also be scanned with special scanners adapted for this method. Both will increase contrast and detail for examination. Gelatin lifts should be photographed immediately after use as some impressions may degrade or dissolve quickly in the gelatin.

Other lifting methods include adhesive lifts, which may be used to lift impressions developed by dusting with fingerprint powder, and casting materials such as Mikrosil™ or dental stone to lift two-dimensional impressions.

Casting

The most commonly used material for casting footwear impressions is dental stone. Dental stone is a gypsum product which is simply mixed with water, poured into an impression, and allowed to harden (Figure 3). Dental stone provides a more durable cast than previously used plaster of Paris materials. This is important because the substrate must be cleaned off the cast before detail is revealed for examination. Dental stone is used to cast all types of three-dimensional impressions, including those in snow. Other materials used to cast impressions in snow include sulfur and sulfur cement. Sulfur materials are melted, allowed to partially cool, and poured into the impression while still in their liquid form. The sulfur quickly hardens, recording the three-dimensional detail of the impression.

Paint or snow print waxes are useful in the casting of certain substrates. Their purpose may be as a release agent, to enable removal of the substrate from the cast, or as a fixative, to provide increased stability of the impression. As previously mentioned, these materials may also provide increased contrast for photography. Care must be employed if used, as they may cause damage to fragile impressions. Most impressions do not require a coating material.

Enhancement

Impressions may be enhanced through the use of specialized photography and lighting techniques and through physical, chemical, and digital processes. Photography and lighting are nondestructive and are utilized first in sequential processing. High-intensity and oblique light are commonly used methods, and alternative light may also be used. The choice of lighting is dependent upon the transfer materials, surfaces, and substrates involved. High-contrast photography or increasing contrast through the use of photographic application software may provide increased detail for examination.

Physical enhancement methods include lifting the impression onto a higher contrast material and powdering impressions with forensic powders such as the conventional black powder. Powdered impressions are photographed in situ, then recovered by lifting with a contrasting material, that is, white adhesive lifter for a black powdered impression. An electrostatic detection apparatus may also be used to detect or enhance indented shoe impressions on paper.

There are chemical methods for the enhancement of both blood and nonblood impressions. The purpose of chemical enhancement is to both develop and increase the visibility of detail and contrast with the background. Blood impressions may be enhanced through the use of stains or chemicals that react with components of blood to produce a color change or the production of light. Amido Black is a commonly used protein stain, leuco crystal violet, and ninhydrin are examples of reagents that produce a color change, and luminol that chemiluminescence when applied to blood impressions. There are a variety of other commonly used blood enhancement reagents.

Other chemical enhancement methods that are used for nonblood impressions include, but are not limited to, the following examples: potassium or ammonium thiocyanate is used to enhance soil residue impressions containing iron, cyanoacrylate followed by powder or dye may be used to enhance wet-origin impressions on nonporous surfaces, and physical developer may also enhance impressions on paper surfaces.

Scene Notes and Documentation

Notes, photographs, and sketches are used to document and record location and observations of impressions at the scene. They are also used in the field to record methods and techniques applied to impressions and observations that are related to the recovered quality of the impression, such as environmental conditions, surface types and possible residue materials or sources.

Elimination Impressions

Individuals who are likely to have left footwear impressions at the scene, and who are not classified as suspects, such as first responders and resident victims, should be asked to submit a photograph of their outsoles for examination. In some cases, test impressions of shoes for elimination may also be requested.

Examination Process

The examination of footwear impression evidence involves the evaluation of the impression and the shoe to be compared, comparison of the characteristics present, and analysis of the similarities and differences observed. Results are reported as an opinion as to whether a particular shoe made or did not make the impression.

Evaluation of the Impression

The impression is examined to determine the characteristics of the impression available for comparison to a shoe. Observations are made in regard to the impression-making and recovery process. If sufficient detail is found in the impression for comparison to a shoe, the comparison to a shoe proceeds. It may be determined by the examiner that insufficient detail is present for a meaningful comparison to be completed. This may be determined at the outset or during the comparison process.

Characteristics Compared in a Footwear Examination

Evaluation of characteristics in a footwear examination includes both class and individual characteristics. Class characteristics are shared by other shoes, and individual characteristics are those considered to be unique to a particular shoe, and are usually the result of damage to the outsole. The ability of an examiner to analyze characteristics is dependent upon the quality and quantity of detail of the impression recovered, and upon the submission of the actual shoes for comparison.

Outsole design

The design of a shoe includes both general and specific design elements. General design is the overall pattern of the outsole as it relates to all sizes of a particular model. Specific design are those elements that may change from size to size or are related to a particular mold, such as particular element intersection with other design elements, or texturing that may relate an outsole to a particular mold. For example, the general design of an outsole may include an arrangement of star-shaped designs around the edge of the outsole, filled with a herringbone design covering the majority of the shoe outsole surface. The specific design may be variable, however. The number of stars, the angle of the herringbone as it intersects the edge, and the number of lines of herringbone covering the length of the outsole may change from one size shoe to another (see [Figure 4](#)).

Physical size

The size of an impression is evaluated on the physical size of the whole outsole, or respective portions of it. Physical size is different than shoe measurement sizes. The evaluation of an outsole's characteristics may result in the determination of a shoe size based on specific design elements. For example, if an impression retains sufficient features to determine a possible shoe model, the manufacturer may be able to provide information regarding the specific design detail that varies between

shoe sizes. If the differences are significant and present in the impression, the source of the impression may be limited to a particular size of shoe. It is noted that design source information should consider the possibility of counterfeit shoes that may mimic, but not follow, the design models of the original source manufacturer.

Wear

As a shoe is worn, the material of the outsole is eroded. The erosion that results in general wearing of areas of an outsole, such as the outer heel, may be used to eliminate or include a particular shoe as a source of an impression, but is not used alone as a basis for identification. Knowledge of the time lapse between the crime scene and the seizure of the shoes is necessary for proper evaluation of wear characteristics. Additional

wear may be expected on a shoe that was collected months after a crime took place, but a shoe that made an impression will never exhibit less wear than is present in the crime scene impression.

Individual characteristics

Specific damage or inclusions to the shoe, such as tears, holes, and stone holds, may be used to identify a particular shoe as the source of an impression (Figure 5). It is the random nature of these added features that makes them valuable to the comparison process. It is highly unlikely that damage will occur in the same position on a shoe of the same design and size and be of the same irregular shape. In combination, these features may be used to distinguish a particular shoe from other shoes. If these features are of sufficient quantity and clarity, it may be the opinion of the examiner that the shoe is the source of the impression.

Method of Comparison

The basis for footwear comparison is the knowledge that direct physical contact between an outsole and substrate produces accurate replication of class and individual characteristics that can be used in a direct one-on-one physical comparison to identify or eliminate compared footwear.

Shoes submitted for comparison are examined and photographed, and multiple test impressions are made of the outsoles of the shoes. Commonly, these test impressions are made on clear film to enable an overlay of the test impression to be conducted. Test impressions are made by dusting the outsole with black powder, applying ink, or using an inkless pad and chemically treated paper. The purpose of test impressions is to provide a replication of the detail an outsole leaves in the impression-making process and to use it as a tool to assist in the comparison of the footwear with the crime scene impression.

The characteristics compared begin with the specific design characteristics and the physical size and dimensions of that design. If differences are found in the design or physical size of the impression as compared to the shoe, the shoe is excluded as a source of the impression. If these are found to

Figure 4 These shoes have a similar general outsole design, but the specific design elements in the forefoot are different. General wear occurs on the outer (lateral) side of each of the heels.

Figure 5 On the left is a portion of a crime scene footwear impression. On the right is a portion of a test impression from a submitted shoe. The corresponding voids in these impressions represent individual characteristics (nicks and cuts) present on the outsole of the shoe (photos not to scale).

correspond, then the comparison proceeds to an evaluation of the characteristics of general wear which can range from a relatively unworn shoe to one that is worn significantly and in specific areas. Evaluation of wear and damage may include consideration of additional wear since the crime scene impression was made, depending upon time elapsed to the seizure of the shoe, as discussed previously. If correspondence is found between the impression and the shoe, the significance is noted.

Comparison techniques

A comparison is conducted between the crime scene impression and the submitted shoe. Test impressions made of the submitted shoe may be superimposed over and/or compared side by side to the crime scene impression. Computer software is also used to superimpose and compare in a similar manner, using digital images of the crime scene and shoe test impressions. Direct measurements using calipers, scales, and other devices may also be utilized during a footwear comparison. Magnification may also assist in the evaluation of small, detailed characteristics.

Levels of Conclusion

The comparison of a shoe to an impression may result in one of the following conclusions: exclusion of the shoe as a source of the impression, identification of the shoe as the source of the impression, or an evaluation of the degree of correspondence of the characteristics.

There are many scales of conclusions in use. Primarily, footwear conclusion scales are similar either to the one published by the Scientific Working Group for Shoeprint and Tire Tread Evidence or to the one suggested by the European Network of Forensic Science Institutes Expert Working Group Marks Committee. Both scales include identification and elimination and a range of conclusions determined by the level of association found.

A primary difference between conclusion scales in use is the application of statistical equations to determine the level of conclusion. A limitation to the application of statistics in the evaluation of footwear evidence is the construction of representative databases.

Examination Notes and Reports

During the processing and examination of footwear evidence in the laboratory, complete, accurate, and contemporaneous notes should be taken to record the actions taken and observations and determinations made by the examiner. Notes should include the original evaluation of the impression, any actions taken to enhance, recover, and photograph the impression, and document that photographs were taken before and after each chemical or physical enhancement, lift, or cast. Written documentation should include the treatment of the shoe submitted for comparison, including the type and number of test impressions taken for comparison. The methods of comparison utilized in the examination, and observations regarding the similarities and differences found should be clearly

documented. This may be accomplished either through written description or by the use of annotated photographs. The conclusions of the examiner should be clearly stated and supported by documented analysis.

The Footwear Expert

The role of the footwear expert is to determine if an item of footwear made or did not make an impression. Often an absolute opinion is not appropriate given the evidence, in which case it is the responsibility of the expert to convey the value and limitations of any found correspondence. To be qualified to make this determination, a forensic footwear examiner should have received specialized training and be experienced in this discipline. Being qualified in other forensic disciplines does not automatically qualify one to examine footwear evidence. Examiners in this field should complete an established training program conducted under the direct supervision of an experienced footwear examiner. Training usually includes study of available literature, successful completion of training courses specific to this discipline, and the working of practical exercises over an extended period of time, allowing the trainee examiner to acquire the necessary skills and knowledge related to this forensic discipline. Touring manufacturing facilities, attending conferences, participating in seminars, and conducting research are additional ways of obtaining further knowledge.

Glossary

Die stamping A male or 'inverse positive' of the character to be stamped is created and then applied to the substrate under sudden pressure.

Embossing Similar to die stamping or rolling but is used on thin metal plates to produce a raised print appearance. The die is pushed on to the plate from behind.

Hot stamping A heated die is used to produce an impressed character in a polymer.

Laser etching The serial number is burned into the substrate by applying a laser.

Nonindustrial engraving The substrate is cut away, leaving marks that form the serial number.

Pin stamping Small pins are used to form individual dots on the substrate, using an impact process; the process is analogous to dot matrix printing.

Radio frequency identification devices (RFIDs)

Encoded chips that are read and deciphered by software when they come into the range of an active antenna.

Rolling A similar process to die stamping, where the characters to be stamped are applied to the substrate with a slower, steadier pressure.

Traditional printing methods A variety of printing techniques can be used to apply serial numbers, especially on adhesive labels or cloth stock.

Introduction

Serial numbers or product identification numbers are present on many everyday objects, from automobile parts to handguns to computers to medical implants. Manufacturers use serial numbers for purposes of quality control, for product tracking, for product liability, and to defeat counterfeiting. The numbers may conform to a standard, such as the universal product code or may be unique to the manufacturer; some products may have both, the latter serving as a batch or lot identifier. In most instances, they are simply a sequential number that describes how many units in a particular production sequence have been produced. In some cases, they are encoded to carry information about the product, such as date of manufacture and model type.

Serial numbers are removed from items in order to hide their true identity. The reasons for the removal are varied and include the following:

- the perpetration of fraud, such as portraying an item to be of a different value when making an insurance claim;
- to hide the origin of items used in the commission of a crime, such as removing the number from a firearm used in a murder;
- to prevent positive identification of stolen property; and
- obliteration through natural taphonomic processes, such as erosion or exposure to extreme environments.

Serial numbers can be applied to objects by the way of adhesive labels or direct transfer to the actual object.

Methods of Application

Serial numbers can be applied in a variety of ways, depending on the substrate to be marked and the environment the number will be used in. The major methods include the following:

- *Die stamping*: In this technique, a male or 'inverse positive' of the character to be stamped is created, and then applied to the substrate under sudden pressure (often by hand). An indented character is left behind. This method is commonly used on metal substrates, particularly in the motor vehicle manufacturing industry. The process is often called 'cold working.'
- *Rolling*: A similar process to die stamping. In this case, the characters to be stamped are applied to the substrate with a slower, steadier pressure. Its application is in cases in which the substrate could be damaged by the sudden impact used in die stamping.
- *Hot stamping*: Polymer substrates are not amenable to either of the cold working methods described above. However, by heating a die before stamping, it can be used to produce a suitable impressed character.
- *Pin stamping*: Small pins are used to form individual dots on the substrate, using an impact process. By arranging these dots into the appropriate pattern, the requisite characters are formed. The process is analogous to dot-matrix computer printing.
- *Nonindustrial engraving*: The substrate is cut away by a tiny spinning head or something similar, leaving marks that form the serial number. This method is particularly common on plastic substrates or where numbers are being applied by a consumer (e.g., inscribing a driver's license number on to the back of a power tool).
- *Laser etching*: A technique that is coming into widespread favor, this effectively involves burning the serial number into the substrate by applying an industrial laser. A residual heat-affected zone with a differential hardness compared to the surrounding material is left behind but is difficult to detect.
- *Embossing*: Involves a technique similar to die stamping or rolling but is used on thin metal plates to produce a raised print appearance. The die is pushed on to the plate from behind.

- *Traditional printing methods:* A variety of printing techniques can be used to apply serial numbers, especially on adhesive labels or cloth stock. The methods include ink processes such as offset printing, hot foil stamping, screen printing, laser printing, etc.

Another type of product identification has developed recently and, with its adoption by large global retailers, it promises to become commonplace and inevitably encountered with – or as – evidence. Radio frequency identification devices (RFIDs) are small chips that are attached to or embedded in a product (Figure 1). The chips can be encoded with large amounts of information relevant to production or stock inventory. The tags themselves are unpowered and ‘passive,’ only able to be read when they come within the range of an antenna; software decodes the tags’ information and relays it to the user. RFID tags are used in many sectors, such as mobile phones, toll road tags, pharmaceutical packaging, public transit cards, consumer goods, casino chips, transportation, asset tracking, passports, medical facilities, and libraries, among others, including forensic evidence tracking. Software specific to the tagging process is needed to read the information on the RFID tag; similar to any digital data or physical serial number, this information is subject to hacking, alteration, and obliteration. Thus, serial number restoration may now also fall under ‘digital evidence’ sections of forensic laboratories.

Removal Methods

Traditionally, methods used to remove serial numbers involve a physical abrasion of the substrate until the number is no longer visible. Methods to do this include filing, grinding (usually with an electric or air-powered angle grinder), sanding with sandpaper or emery paper, or scraping with a sharp implement, especially on plastic substrates.

Numbers can also be obliterated so that they are no longer decipherable. One method of accomplishing this is called ‘peening.’ A relatively sharp object, such as a center punch or cold chisel, is hammered on to the area of the number until it is damaged beyond legibility.

In the case of printed numbers, chemicals can be used to wash away or blur the numbers. Solvents such as alcohol, acetone, or similar compound can be used.

Restoration Methods: Metals

Forensic practitioners are often confronted with die-stamped serial numbers that have been ground off metal substrates. This is particularly common in cases involving theft of motor vehicles or the use of firearms.

If a number is ground off a surface until no visible sign of the characters remains, it does not necessarily follow that all traces of the number have been obliterated. The process of cold working involves transmitting a shock into the substrate, and compressing the metal structure such that the material, which originally occupied the volume taken by the characters, is displaced downward into the substrate (Figure 2). If the top layer of the substrate is subsequently removed, a damaged area of material underneath the original characters may remain (Figure 3). Note that a number of factors may influence how far into the substrate the damaged area extends. These include the composition of the material, as well as the force used to stamp the number. If the surface is ground off deeply enough, it is possible that all traces of the damaged area will be obliterated.

There are two major methods employed for recovering obliterated serial numbers in metal substrates. These are generally referred to as ‘chemical etching’ and ‘heat treatment.’ The purpose of both processes is to create a visible contrast between the damaged and undamaged regions of the substrate. This contrast is the result of differential reflection or scattering of light from the damaged area compared with that from the undamaged area (Figure 4).

Figure 2 Damaged area underneath a stamped character.

Figure 3 Residual deformation still present after obliteration of character.

Figure 4 Reflection of light from smooth surface compared to rough surface.

Before either method can be applied, the surface must be prepared. This involves removing as much as possible in the way of residual irregularities, in order to obtain as smooth a surface as possible. A compromise must occasionally be reached when deep grooves are present, as removing the surrounding metal may achieve total obliteration of any remaining traces of the original characters.

Progressively finer grades of waterproof abrasive paper (known as 'wet and dry' paper) should be used to gradually smooth out the surface, with the best results being obtained from a mirrorlike finish. Some practitioners use small hand-grinding or sanding tools to smooth the surface, but this can run the risk of uncontrolled heating of the area, as well as having less control over the depth of the abrasion. For these reasons, hand sanding is generally preferred.

Chemical Etching

This is perhaps the most commonly used technique for recovering obliterated numbers. It originates from metallurgical examinations, in which etching solutions are applied to cross-sections of metal in order to observe the crystal structure under reflected light.

For recovering obliterated numbers, the method relies on the phenomenon that the rate of reaction between the applied chemicals and the substrate can differ in the damaged and undamaged areas. The damaged area usually has a different electrochemical potential to the undamaged surroundings, so can therefore be attacked selectively, or at least at a different rate, in comparison with the surroundings.

The chemicals used depend on the composition of the substrate. They range from simple alkaline solutions to complicated mixtures, which result in an oxidation/reduction reaction with the metal. Care must be taken when using some of the etching solutions, as they can be corrosive and/or toxic.

The solutions are generally applied by wiping them across the surface of the substrate with a cotton wool or cloth swab. This process is repeated regularly, and the surface is observed closely between applications. Any visible characters should be noted immediately, as it is quite common for different characters to appear at different times during the restoration. It is also common for some characters to disappear shortly after becoming visible.

Another method of application, particularly useful for aluminum alloy engine block numbers on horizontal surfaces, is to form a dam of plasticine around the area, then pour the etching solution into this to a depth of 2–5 mm. The surface will be observed to bubble, with the recovered characters being visible.

A modification to the standard chemical etching technique is that of 'electropolishing.' This involves adding an electric current to the etching process. A DC power supply is used, with one terminal connected to the body of the substrate, and the other to the swab. This method has found favor in some forensic laboratories, but opinion seems to be divided. In many instances, the extra time and equipment required are considered not to produce a superior result.

Heat Treatment

This is a highly successful technique, with particular application to restoring obliterated serial numbers on cast-iron

substrates. It has one significant advantage, which is speed. A heat treatment can at times be completed in a matter of minutes, whereas chemical etching is generally a much slower process. It again relies on the residual stresses remaining under the stamped area. However, the visualization technique differs from that of etching. In this method, heat is applied directly to the obliterated area until the metal glows a light cherry red. This results in the release of the residual tensile stresses and allows the compressed area to bulge above the surroundings (Figure 5). After heating, the area is lightly rubbed with abrasive paper, which removes any soot or oxide layer from the raised characters. They therefore stand out in contrast to the dark surroundings.

There is no specific temperature at which a heat treatment recovery will take place. Factors including the depth of the impression and the exact composition of the substrate will affect the temperature required. As a guide, the surface should be slowly heated to no more than a cherry red. An oxyacetylene welding torch with a small brazing tip, such as a number 8, is the preferred heating equipment.

It is sometimes possible to see the raised characters before the surface has reached full temperature. If this occurs, there is no requirement to heat further.

In order to avoid cracking the substrate, the area should be heated slowly, and then also allowed to cool slowly. To do this, the heat source should be either gradually turned down or slowly moved away from the surface. This avoids a rapid cooling process.

Heat treatment has been used with limited success on aluminum alloy substrates. A much lower temperature is employed, and it appears preferable to apply the heat to the substrate a short distance away from the obliterated area and allow conduction to heat the area in question. This is known as 'indirect heating.'

For thin sheet metal areas, the application of heat treatment does not seem to produce useful results: chemical etching is the preferred technique.

Other Methods

A variety of other methods for visualizing obliterated serial numbers on metal objects have been reported but are not in general use. These include the following.

Magnetic Particle Method

In this technique, the object is magnetized and then sprayed with fine magnetic particles. The particles are attracted to regions on the surface, where a crack or other damage has occurred. The method has an application in crack testing of aeronautical components and is suitable for the recovery of serial numbers on small objects such as firearms.

Figure 5 Bulging of surface following release of residual stress due to application of heat.

The method has an advantage, in that it is nondestructive, enabling other methods to be tried subsequently if necessary. It does, however, have a significant drawback, which is in the equipment required. To magnetize, the object requires either running a high amperage electric current through it or placing the object in contact with a large magnet. Also, neither of these actions is appropriate if the object happens to be a serial number stamped on an engine still fitted into a motor vehicle.

Ultrasonic Cavitation

Cavitation is a phenomenon that involves the formation of bubbles in a liquid because of localized reductions in pressure. The bubbles are of high energy and have the capability to etch metal surfaces.

Recovery of obliterated serial numbers in metal objects is possible if they are placed into a water bath, which is excited by an ultrasonic sound frequency. It appears that the etching occurs preferentially at the sites that have been damaged by stamping. The method has the advantage of being applicable to a wide variety of metals and not requiring the use of chemicals. However, similar to the magnetic particle method, it is only suitable for small objects. It is also destructive, in a similar manner to chemical etching.

X-Rays

The use of radiography in efforts to recover obliterated serial numbers does not appear to be successful. It seems that the radiographs are simply not sensitive enough to enable visualization of the minute damaged areas left after removal of a number. However, the method has been successfully used to locate serial numbers that have been hidden with paint or body filler, or by welding another piece of metal on top of the original.

Restoration Methods: Plastics

A stamped polymer retains a compressed area underneath the characters in a manner analogous to that of metal substrates. To recover the number, it is necessary to apply a method that will swell the substrate, allowing an image of the compressed area to become visible. The methods used to achieve this include applying heat (obviously at a considerably lower level than that applied to metal), polishing, or immersing the area in chemicals. The results from these approaches vary depending on the composition of the polymer, and many of the chemical methods use potentially hazardous reagents that may be damaging to the evidence. One safe chemical alternative, discovered by Katterwe and advanced by Burke et al., is clove oil of which the active ingredient is eugenol.

Reagent Recipes

There are numerous formulations for chemicals that will etch different metals. For practical purposes, the major ones of interest are described in [Table 1](#).

A variety of chemicals can be used to swell polymer substrates ([Table 2](#)).

Table 1 Common metal etching formulations

<i>Substrate</i>	<i>Etchant</i>
Cast-iron and steel	1. Fry's reagent 90 g CuCl ₂ 120 ml HCl 100 ml water
	2. Modified Fry's reagent 15 g CuCl ₂ 120 ml HCl 75 ml ethanol
Stainless steel	1. Acidified ferric chloride 5 g FeCl ₃ 50 ml HCl 100 ml water
	2. Dilute sodium hydroxide 10 g NaOH 90 g water (Some sources suggest up to 60% NaOH)
Aluminum alloys	1. Hume-Rothery's solution 200 g CuCl ₂ 5 ml HCl 100 ml water
	3. Dilute nitric acid 25 ml HNO ₃ 75 ml water
Brass and copper	4. Alternating acid and alkali 10% NaOH and 10% HNO ₃ applied alternately
	1. Acidified ferric chloride 19 g FeCl ₃ 6 ml HCl 100 ml water
	2. Copper chloride solution 40 g CuCl ₂ 180 ml HCl 100 ml water

Table 2 Chemicals used for the restoration of obliterated serial numbers in common polymers

<i>Substrate</i>	<i>Chemical</i>
High-density polyethylene (HDPE)	Ethanol
Polycarbonate	Ethanol, ethyl ether

Photography

The photographic techniques used to record recovered serial numbers are applications of those used in other forensic areas, such as fingerprints and crime scene examination.

For photographing, the results of a chemical etch, black and white imaging has proved to be most suitable. It allows for the contrast between the faint image and the background to be enhanced. A mixture of flash photographs and available light images should be obtained where possible. Oblique lighting appears to produce the best images. It is often necessary to experiment to determine the best angle for the incident light, depending on the extent of the recovery, and the nature and location of the surface. A film speed setting of 400 American Standards Association (ASA, now the American National

Figure 6 Lighting used for photographing the results of heat treatment.

Standards Institute) is suitable, in order to produce images from faint recoveries.

The nature of the recoveries obtained by chemical etching does not always lend themselves to photography. It is possible in some instances to obtain a faint recovery that is decipherable with the naked eye but will not produce a satisfactory image. Image processing may be required, either in a dark room or with software. This reinforces the fact that careful, detailed notes should always be maintained throughout an etching process.

For recording, the results of a heat treatment, a speed setting of about 200 ASA has been found to be appropriate. Again, a mixture of flash and available light photographs should be taken. Interestingly, the results from flash photography appear to be superior in this situation. The best results are often obtained by having the flash unit as closely aligned as possible to the lens of the camera, so that it is almost projecting vertically on to the surface (**Figure 6**). This appears to highlight the

reflective tops of the raised characters and can result in some spectacular images.

Introduction

As a shotgun fires cartridges loaded with pellets, the charge emerges from the muzzle *en masse* and travels as such for about a couple of meters; then, the pellets begin to disperse, decreasing the number of pellets actually striking the target. The dispersion of the shot is clearly a function of distance, and the recognition of this relationship permits the determination of the distance between the firearm and the target at the instant of discharge. This estimation of the firing range, usually expressed from the muzzle end of the gun barrel to the target, is an essential element of the investigation. Generally, the distribution of pellets on a target allows for determination of the range of fire, up to 20 or 30 m with considerable accuracy. At these distances, the shotgun pattern has no other characteristics (such as tattooing, blackening, burning, presence of a gunshot residues pattern, etc.) that could also be used for the determination of shooting distance. At closer ranges, the firing distance evaluation by shot dispersion can be complemented by analysis of the gunshot residues pattern (by optical methods and by means of specific chemical tests) and/or by exploiting others of the characteristics mentioned above.

The degree of dispersion of the shot depends on many factors, the most important of which are the type of pellets, the cartridge pressure, the wadding, the barrel length and the extent of choke. A complete analytical solution to the exact pellet dynamics is a very complicated problem, that includes dynamic forces, constraints, and boundary conditions not completely known.

The Shot Shell

In order to fully understand various aspects of the degree of pellet spread, it is important to explain the different components of a shot shell. A shot shell consists of a cylindrical casing containing the powder (mostly smokeless), the charge (pellets or slug), and one or more wads; buffer material is sometimes present. The mouth of the cartridge is closed either by a crimp closure or an overshot wad.

The Pellets (or shot)

Currently, four types of shot are available on the market: drop or soft shot (essentially pure lead), chilled or hard shot (hardened by the addition of antimony), steel shot and plated shot. Individual steel pellets weigh less than comparably sized lead pellets and thus have a less range; plated shot is lead shot coated with a thin coat of copper and/or nickel to minimize distortion on firing, thus maintaining a good aerodynamic shape and increasing the range. Other softer, nonlead materials

(e.g. tungsten in an organic polymer, bismuth/tin alloys, molybdenum, zinc alloys, etc.) have been tried or used recently in an attempt to increase the ballistic performance of the shot. If patterns caused by the different types of shot are examined, it appears that the harder shot gives a more uniform distribution of pellets.

Buckshot pellet patterns may be influenced at short distances by the stacking order of the pellets in the cartridge case, appearing as a series of superimposed triangles on the pattern (**Figure 1**).

The velocity of the shot at the muzzle of the firearm is a parameter influencing the distribution of the pellets. The velocity of the shot is itself determined by the burning of the propellant powder and the length of the barrel. For traditional shot shells, the higher the pressure generated by the cartridge, the more the shot will be disrupted as it emerges from the barrel by the following gases. While this effect is largely offset by the wads used in modern cartridges, it is a factor that does affect the dispersion of a shot.

Apart from the ammunition for shotguns with smooth barrels, special rounds with shot charge exist for handguns and rifles, more particularly in calibers .22 LR, .38 Special, .44 Magnum, .45 ACP, and 9 mm Luger. Flobert cartridges loaded with shot are also available.

The Wadding

The wadding in traditional shotgun cartridges consists of an overpowder wad, a series of filler wads, and an overshot wad. This construction suffers from a number of drawbacks, which can lead to distorted and enlarged patterns on the target. In fact, on firing, some hot gases from burning powder are able to bypass the overpowder and filler wads to reach the shot charge; these gases partially melt and fuse together a number of pellets. Likewise, the filler wads do not provide sufficient cushioning of the shot to prevent distortion due to intershot contact; in extreme cases, the rapid acceleration of the shot charge causes pellets at the bottom of the charge to be 'welded' together by the pressure into small clumps. Apart from this effect, the filler wad can fly into the rear part of the shot and scatter it.

Furthermore, during the passage of the shot through the barrel, pellets in contact with the inside surface of the bore are distorted or abraded as a result of both pressure and friction. Deformed or abraded pellets are aerodynamically less stable because they will suffer greater effects from air resistance. Consequently, they will not retain as much speed and energy, resulting in a trajectory deviating from the flight path of the main body of shot. These so-called 'fliers' are present in all shotgun patterns and can also be due to irregularly shaped shot, or pellets that become imbedded in the wads, etc.

Figure 1 Cross-section of a shot shell containing buckshot pellets.

Long-shot columns aggravate the conditions described, thus leading to increased pellet deformation and hence a greater occurrence of fliers.

Another impairment to a good pattern is the overshot wad; this is supposed to slide off to one side of the shot column as it emerges from the barrel. This does not always happen, and the overshot wad sometimes remain in the shot column, disrupting it and causing a cartwheel pattern. If the overshot wad is found on the target, it is an indication of a close shot.

Modern wads tend to be of the plastic cup type with an integral shock absorber and gas seal (**Figure 2**). The shock absorber consists of a semicollapsible section that very effectively cushions the shot column at the moment of acceleration. The integral plastic cup protects the shot during its passage through the bore and the plastic gas seal prevents the leakage of hot gases into the shot column. Cartridges loaded with this type of one piece wad (monowad) will give a much more controlled spread of shot than one loaded with the old type of wad column. The walls of the cup are split so that after exiting the air pressure divides the walls into sections, resulting in more air resistance while not disturbing the trajectory of the shot. Crimping or folding of the casing material eliminates the necessity of having an overshot wad.

Shotgun wadding trajectories

When a shotgun is fired, the trajectory of the different compounds of a wadding depends on its weight and shape. The wadding can be projected to 30 m or further and it can deviate from the center of the flight path of the shot. The lighter weight for a less aerodynamic shape enhances the air resistance, so that the total length of the trajectory is considerably reduced. As the wadding strike effects can sometimes be extremely reproducible, they allow the forensic scientist to conduct firing tests to determine the range of firing.

Apart from the shooting distance determination, the examination of the wad will give an indication of the caliber of the shotgun and the make of the ammunition.

The buffer material (or granulated filler)

The buffer material, mostly made of polyethylene or polypropylene and found primarily in larger birdshot and in buckshot loads, cushions the shot pellets on firing, reducing shot distortion and improving the shot pattern. The filler accompanies the shot toward the target and can produce stipple marks on the skin identical in appearance to powder tattoo marks. Marks from the filler can vary from large and irregular, to small and regular, depending on the size and shape of the granules. Buffer material can be consistently deposited on targets up to 4.5–6 m from the muzzle, and along the ground, the distribution of buffer may be seen up to about 9 m. The distribution diameter of buffer also shows linear expansion as a function of range of fire. The rate of expansion is, however, far in excess of the pellet distribution diameter, resulting in a near constant buffer distribution diameter beyond about 3 m. Crosswind can produce significant distortion in the buffer distribution, and therefore range of fire estimations based on this parameter should be approached cautiously.

The Barrel

Shortening the barrel by sawing off the end of the muzzle does have some effect on the spread of shot. What effect exists, however, is mainly due to the high-pressure gases disrupting the shot column as it exits from the barrel. Shotgun propellants are very fast burning, giving rise to a very sharp increment in pressure during the first few moments of ignition. In full-length barrels, the overall pressure within the barrel drops very considerably as the shot nears the muzzle, and the volume of gas between the over-powder wad and the breech of the weapon increases. As the barrel is progressively shortened, the pressures being exerted on the base of the shot column as it exits the barrel become progressively greater. These pressures can lead to a destabilization of the shot column, resulting in a 'blown' pattern; this effect, which increases with each shortening of the barrel, can be identified by an irregular shot pattern and a larger spread than would normally be expected. For some brands of cartridges, this increase in spread of the pattern is important; for other brands of ammunition, the spread remains constant.

Another effect of shortening the barrel is to remove the effect of the 'choke'.

The Choke

Most shotgun barrels have a constriction applied to the muzzle end of the weapon's bore so as to control the spread of the shot. This constriction is called 'choke' and may start anywhere from 2.5 cm (1") to 15.2 cm (6") from the end of the barrel. The choke constricts the diameter of the shot column, increasing its overall length as well as the velocity of the pellets at the front of the shot charge. The cone-shaped reduction in the barrel results in the outer layers of shot in the column being

Figure 2 Different designs of plastic cup wads.

Table 1 Percentage of shot at 36.6 m in a 76.2 cm diameter circle, according to the different chokes

Boring of gun	Percentage of shot
True cylinder	40
Improved cylinder	50
¼ choke	55
½ choke	60
¾ choke	65
Full choke	70

given an inward acceleration, which delays the spreading of the shot once it leaves the barrel and reduces its tendency to separate in flight. A certain number of pellets suffer some deformation in the process, both from friction with the barrel walls and by their interaction with each other.

Some barrels intended for use at close ranges are bored without choke and are referred to as being bored 'true cylinder'; the lightest choke in the English system is referred to as 'improved cylinder' (0.12 mm), followed by 'quarter choke' (0.25 mm), 'half choke' (0.50 mm), 'three-quarter choke' (0.75 mm) and, finally, 'full choke' (1 mm). It should be noted that American and Continental choke designations are slightly different. Different degrees of choke will give different patterns for a particular shotgun charge; the tighter the degree of choke, the smaller the pattern of shot at the target. At a similar range and assuming the same barrel length, cartridge type and pellet size, all bores with a given choke having different calibers (with the exception of the .410) produce approximately the same size patterns. Obviously, the patterns will differ in density.

The degree of choke is based on the percentage of pellets that will stay inside a 76.2 cm (30") circle at 36.6 m (40 yards), with exception to the .410 shotgun, in which the pattern of shot is determined in a 50.6 cm (20") circle at 22.9 m (25 yards). **Table 1** gives the percentage of shot that can be expected for the various choke borings. There are slight variations, which depend upon the size of shot used; if cartridges of different shot size are loaded to the same average velocity the large shot will show a better result. It should be stressed that the percentages of **Table 1** may be higher when using modern ammunition because of improvements in shot shell design. This improvement in pattern performance is true for all chokes and it decreases with smaller shot sizes.

In addition to the barrel choke and barrel length, the condition of the bore (either smooth or rifled, corroded, damaged, etc.), the length of chamber cone and the size of the chamber will affect the pattern. For example, if the bore of a gun has become pitted due to corrosion, it will increase the friction of the shot.

Shooting Range Estimation

At ranges of within 1 m, the pellets are still travelling as a compact mass, thus the entrance hole will be a single perforation of large size (approximately 2–3 cm). Contrary to intuition, it is frequently not possible to determine accurately either bore or shot size. As the range increases, the edges of the impact will have scalloped margins. Still farther away, the pellets start to disperse, leaving scattered satellite pellets holes around the central impact. The separation and the number of these pellets will increase with increasing distance. At distances of about 3 m, buckshot pellets cause isolated impacts.

The question of correlating range with pellet dispersion is usually approached with the assumption that the entire distribution of pellets is available for examination. In practice, the target usually reflects only a portion of the pattern and thus the range estimation is seriously limited by the size of the target. Due to the relatively small size of the average human target, this applies more particularly to victims. In this case, it is impossible to estimate the range from a measurement of the whole pattern diameter; the only measurements available are the distances between a limited number of pellet holes, and the estimation of shooting distance is scarcely reliable. Partial pellet patterns sometimes allow the examiner to position the victim within the void characterizing the pellet pattern present on the crime scene.

Where more than one shot has been fired, one should be very reticent in making any positive range determination. Another important aspect is the way the target was exposed to the charge of shot at the time of shooting. In fact, when the pellets strike the surface at an angle of incidence other than 90°, the density will appear less.

Considerable effort has been devoted to the development of empirical and mathematical models to describe the dispersion of shot from the discharge of a shotgun; many formulas have been published, but several workers have questioned their applicability. The only reliable method of determining range is to obtain the suspect weapon and a sufficient quantity

Figure 3 Shot dispersion recorded on paper sheets at various muzzle-to-target distances: (a) 2.5 m; (b) 5 m; (c) 7.5 m; and (d) 10 m. A 12/70 Mossberg 500A true cylinder riot gun was used to fire Sellier and Bellot shot shells containing 32 g steel shot with a diameter of 3.5 mm.

of rounds of the same brand of ammunition believed to have fired the questioned pattern, and then conduct a series of test shots so as to reproduce the pattern of the shooting incident. The best test ammunition is that belonging to the same batch as the cartridge of the crime. The pellet patterns can be recorded on butcher paper targets at different distances from the muzzle (Figure 3). If buckshot shot shells are used, the patterns at different distances can be recorded at the same time by using an in-line array of several thin paper targets placed at known intervals from the muzzle of the shotgun. Although such an approach seems rather unsophisticated, it is capable of a remarkable degree of accuracy.

The generalizations available in the literature provide only a very rough estimate, as the variations of the type of powder, type of load, length of the barrel, degree of choke, etc. are too great. For example, some researchers have shown that two lots of ammunition manufactured within days of one another show similar ballistic performances, while those manufactured months apart have very different ballistic performances. The conditions in which shot shells have been stored may seriously compromise the determination of distance; shot shells that have been stored in cold weather may produce pellet patterns

on a much more restricted range than those stored under more 'normal' conditions. In fact, the reduced temperature produces a slowing down of the burning process of the gunpowder, which reduces the pressure in the barrel chamber and lowers the velocity of the shot. Consequently, there is less natural deformation of the pellets, which results in less air resistance and smaller dispersion of the pellets, at least at close distances.

Should there not be enough rounds available, a useful range of fire estimation can be obtained by firing a different brand of ammunition. A scaling factor allows one to transform the results, based on a comparison of the patterns obtained with the two different ammunitions at the same distance.

The test shots on paper provide a permanent record of the effects of blackening, tattooing, burning, powdering, buffer, and wadding impact marks as well as pellet spread. One has to take into account that no shotgun/shot shell combination will fire exactly the same size pattern at a given distance repeatedly, and also that some guns and loadings will pattern more uniformly and with greater regularity than others. It is therefore advisable to illustrate the variation in pattern size at a given range by carrying out a sensible number of test firings. In practice, it is suggested that at least three shots should be

fired at each test distance; of course, the more shots fired at a given distance, the more accurate the findings will be. Generally, as the distance from the muzzle to target increases, so does the amount of variation in pattern size. The larger the variation between shots, the larger the range of distances at which the shot could have been fired.

The spread of the pellet pattern can be characterized by using several parameters, based on the measurement of a characteristic length or number. The most common among them are:

1. The area or the square root of the area of the smallest rectangle that encloses the entire pellet pattern.
2. The greatest average diameter (or greatest diameter method), which is the measure of the distance between the outermost pellets in the pattern that enables the determination of the average diameter of the pattern.
3. The radius of the smallest circle enclosing the total pattern.
4. The equivalent circle diameter (ECD), which corresponds to the circumference of the polygon formed by the outermost pellet holes divided by π .
5. The distances between pellets within the pattern.
6. The effective shot dispersion (ESD) = $\{(4/N_o)\sum R_i^2\}^{1/2}$ where N_o is the total number of pellets and R_i is the radial distance of the i -th pellet from the center of the pattern.
7. The percentage of shots being dispersed outside a circle of a certain diameter about the pattern center.

In all these measurements, flier pellets have to be discarded; it is not uncommon for fliers to increase the actual pattern diameter to twice that of the bulk of the shot charge.

The number of pellets to be accounted for will influence the choice of a particular technique. In this article, we will shortly digress on techniques (4) and (7), as we feel they are well suited for buckshot and birdshot, respectively.

For a large number of pellets, their distribution around the center should be rotationally symmetric, while the radial component r reflects a gaussian distribution. Recent experiments have cast doubt on its gaussian character for the central region of the distribution. Given the large number of pellets and the fact that we are merely interested in the outward region, the probability of finding a pellet at a distance r to the center is given by:

$$p(r) = \sqrt{\frac{2}{\pi}} \frac{1}{\sigma} \exp\left(-\frac{r^2}{2\sigma^2}\right)$$

The proportion of pellets falling within a circle with radius r is given by the integration from 0 to r . In this formula, σ is the width (mean deviation) of the distribution. The factor $\sqrt{2/\pi} \cdot 1/\sigma$ ensures that the distribution is properly normalized at integration of all radii $0 < r < \infty$. Hence, all the pellets can be expected to be found only within a circle having an infinite diameter. For a circle with a given radius, the incident proportion of pellets is given in Table 2. This table provides a means of determining by measuring the radius of the circle containing 95 or 97% of the pellets.

A statistical analysis of the results obtained by the greatest diameter method (2), as well as from the ECD method (4), show that the ECD method gives the most reliable results.

Table 2 Percentage of pellets within a circle with a given radius around the center of impact

Radius	Percentage of pellets
σ	68
1.64σ	90
2σ	95
2.17σ	97

Confidence limits can be obtained by performing a statistical analysis on several test firings or by simply taking the upper and the lower limit of a limited set of values. In the latter case, the obtained confidence will depend on the number of test firings. The results can be plotted on a graph (width versus range of fire), together with the confidence levels. The pattern found on the crime scene can be converted to a range of fire with a corresponding confidence limit (maximum and minimum likely ranges of firing) using this graph or after performing a linear regression analysis. This graphical solution accounts for the lack of confidence limits available for the pattern present on the crime scene.

Intermediate Targets

Shot charges may strike an intermediate target such as a pane of glass, a screen, or an arm before impacting the final target. This intermediate target will increase the dispersion of the shot and a disproportionately wide spread is observed as long as the majority of pellets hit the target *en masse*. An explanation for this phenomenon may be that pellets, particularly at close ranges, are deflected by striking each other during their passage through the intermediate target, with the resulting effects possibly enhanced by the initially higher velocity. Contact or close-range wounds may create a similar effect inside the body. In cases where the pellets pass through an intermediate target, the only way to determine the range correctly is to interpose a similar target when firing. In some cases, no reliable firing range determination can be made. Heavy clothing can act as an intermediate target, enlarging the pellet pattern present on the body of the victim. For decomposed or burned bodies, it may seem convenient to obtain the pellet pattern using X-rays but experiments have shown that this method is completely unreliable.

Intermediate targets may also reduce the number of pellets in the pattern by ricocheting or stopping the pellets, as, for example, occurs when trees are in the line of fire.

Adaptations

Certain adaptations, to both gun and cartridge, can be employed to increase the shot spread. Special slow twist rifled barrels are made for such purposes; special shot spacers can be used in the cartridge loading; some devices, called shotgun diverters, can also be attached to the muzzle end of a shotgun in order to change the normal circular pattern of shot to a controlled, predictable, rectangular, or ellipsoidal pattern, the notion being that the increase in lateral spread will give a higher probability of hits.

Some Misconceptions

One common misconception is that the distance, in inches, from the center of the pattern to the point where the wads hit the target gives the range in yards. This is totally untrue and should never be used for estimation of range of firing. Another misconception is that in heavy rain the pellets will be disrupted by the raindrops.

Glossary

Daubert ruling In 1993, the United States Supreme Court issued an opinion relating to how federal judges should decide whether to allow expert testimony into the courtroom. This ruling replaced the former ruling from 1923 known as Frye in parts of the country.

Error rate An error rate is the calculated chance of reaching an erroneous answer to the tested question.

Isotropic material The term is used in material science and means uniformity of crystallographic structure that has

identical values of property, such as conductivity or elasticity, in all directions that are the same regardless of the direction of measurement.

Plastic deformation Describes the deformation of a material undergoing nonreversible changes of shape in response to applied forces. It is caused when the applied force is stronger than a critical value, depending on the qualities of the specific material. It can be observed in most materials including metals, soils, rocks, concrete, foam, bone, and skin.

Introduction: What is a 'Physical Match'

A physical match is defined by the Association of Firearm and Toolmarks Examiners (AFTE) Standardization Committee as 'the examination of two or more objects, through physical, optical, or photographic means, which permits one to conclude that the objects were either one entity or held bonded together in a unique arrangement.'

Usually physical match is viewed as one of the strongest ways for establishing common origin. Physical match has a long history of acceptance in courts of law, and in the forensic literature, it is often regarded as strong conclusive evidence.

Physical matches can be found in numerous cases and in different materials such as glass, plastic, and metallic objects.

The recognition of a physical match is very intuitive for laypersons, and when achieved, or shown in court, is easily understood. This kind of evidence straddles the borderline between 'common knowledge' and a proven 'scientific rule.'

A practical question often asked is 'what is the minimum length of the contour, combining the two parts that can establish a positive identification?'

Another way to ask the question is 'what is the minimal information content of the match needed to ensure that the probability to see a different, wrong match as the correct match is negligible.' When the matching surface is large or the matching fracture line is long, the amount of information is sufficient, and there is no doubt that the match is correct. The pieces will fit together in a manner that will convince every layman of the true match.

Below are presented some examples:

Stolen Objects

A generator was stolen from a construction site. A metallic base broken from the main device of the generator remained in the site. When the suspects were arrested with a baseless generator – the physical match between the two broken metals set the link in a convincing way (Figure 1).

The amount of information within the match might not suffice to establish a conclusive link. The problem of

insufficient information may arise on several occasions: plastic deformation, loss of material during the breaking, or very small pieces to be matched.

Deformation of Adhesive Tapes

During a protest rally, a hand grenade was thrown into the marching crowd. Intelligence sources led to a suspect and a roll of adhesive tape was found in his possession. The edge of the tape matched the edge of the tape that was wrapped around the hand grenade. The match was approximate – because of the deformation of the edges of the adhesive roll. Tearing vinyl tapes with manual force often creates severe deformation on the edges of the tape, making the physical match difficult (Figure 2).

Absence of the tear or breakage area is very common in rigid objects and fabric matching. This can be demonstrated by torn pieces of paper or cloth, where some small pieces may be missing because many fibers are detached from the tear area. Ceramic fragments (archeological remains) are prone to a similar problem, small grains having been removed from each matched piece over the years. In such cases, the context (letters, shapes, lines running across, etc.) plays a major role in establishing a match. This can be demonstrated by an example of a torn piece of cloth found at the entry point of a burglary. The fibers are very loose on the edges, but the overall view is convincing, mostly because of the exact size, the advancing of the tear, and the design on the trousers (Figure 3).

Another example shows the problem of two small fragments of the front light of a car. The match between two pieces was along a very short length (several millimeters), and the match relied on the context as well and not solely on the actual dimensions of the breakage area.

Car Accident

In a 'hit and run' accident, a pedestrian was run down by an unknown vehicle and died in the hospital. A fragment of plastic from the vehicle's front light was recovered from his forehead. At the scene of the crime, more broken plastic pieces

Figure 1 Physical match between two broken metals.

Figure 2 The match between the edge of the tapes: the suspect's and the one that was wrapped around the hand grenade.

were collected. A suspect vehicle was found, and the front head light was brought to examination. The broken pieces from the scene of crime were visually similar and physically matched the remains of the plastic on the broken head light. In addition, the small plastic fragment found stuck in the deceased forehead matched the other broken plastics as well!

The connection between the vehicle, the victim, and the scene of crime was established (Figure 4).

The problem of mathematically finding the lower length limit for a positive match has not yet been solved. It has been said about glass fragments: 'No two broken edges will match perfectly over any extended length. If an edge match that extends over reasonable length, for example, a quarter inch or more, can be found, it is virtual proof that the questioned fragment was broken from the exact spot in the original...' The quoted length (1/4 in.) has no mathematical basis or proof. For other materials, the authors did not find any numerical parameter in scientific forensic literature to determine the minimal length (or minimal information content) required for a positive identification.

The rules for the admissibility of scientific evidence have changed in the last decades. In the United States, the *Daubert v. Merrell Dow Pharmaceuticals* decision (509 U.S. 579 (1993)) asks the trial judge to consider the known or potential error rate of a scientific theory or procedure when determining the

Figure 3 Physical match of fabric: (a) the small piece of fabric found at the scene of crime, (b) the torn trousers found in the suspect's possession, and (c) the match.

reliability of the theory or procedure for admissibility into the courtroom. An error rate is the calculated chance of reaching an erroneous answer to the tested question per the ground truth of the test material. The error could be an inherent outcome of the used technique itself or the error can occur in the conduction of the measurements that lead to the conclusion. The mistake could be a 'false positive,' when a positive identification is established, but the ground truth is that the objects come from different sources. In forensic science, this can have a very serious impact on the case, and an expert is expected to

Figure 4 A and B: the broken pieces from the scene of crime that matched the remains of the plastic on the broken signal lamp. The small plastic fragment found stuck in the deceased forehead (marked “C” in the middle) also fit into the match.

never make this type of error. The other type, a ‘false negative’ is when there is a true match, but the expert concludes that this is not a match. This kind of mistake has been viewed by the judicial system as less egregious, although it can also have a serious impact on the case.

While there are still some forensic scientists who insist that an error cannot occur in their laboratory, the majority of forensic scientists know that there is not a single measurement without some scientific degree of error, actual or potential. Knowledge about the ‘potential or known error rate’ is essential in presenting the evidence. The way to show the error rate in a physical match is yet to be developed.

The Uniqueness of a Fracture Line

Experiments showed that tearing or breaking various materials under controlled conditions results in different fracture lines. This phenomenon is an outcome of the isotropic nature of the material. It is intuitively understood that a material with internal structure might break along fixed lines, resulting in very similar breakage lines in several repetitions of the experiment. If the force is advancing without a predetermined line, then we would assume a random move in this material. However, every material has its own ‘characteristic behavior.’ This phenomenon leads to partial tearing lines, or broken edges, that have similar (but not identical) patterns.

In every examination, the expert must be aware of the unique pattern that characterizes the breaking or tearing process of the specific material at hand.

While it can be argued that on the microscopic level, each tear pattern will be completely different, in the practical aspect, it may be impossible to visually distinguish between the two fracture lines.

The advance direction and shape of the shear are dependent on the applied force and the characteristics of the torn substrate: crystalline, preferred crystallographic orientation (rolling or extrusion process), or amorphous.

A crystalline material is defined as a material in which atoms are arranged in a periodically repeating geometric array. Deformation by rolling or extrusion causes the grains

to develop a preferred crystallographic direction parallel to the rolling direction, which causes isotropic grain boundary dimensions. These production processes stretch the grains in the production direction. Materials that do not have the long-range repetitive pattern of crystals are called ‘amorphous’ materials. They are nonisotropic polymer chains that are long and flexible macromolecules; they are all mixed together resembling a bowl of spaghetti.

In general, shearing will advance on a macroscopic scale in the direction of the applied force. The specific nature of the tear is derived from the applied shearing stress and from the nature and microscopic structure of the torn material. Since the microscopic structure is unique, and it is practically impossible to repeat the exact force and direction of the tearing, the basic axiom in physical match claims that a tear or breakage is unique and will not repeat itself even under the same conditions.

Obstacles to Performing a Physical Match

When trying to find if two or more pieces were assembled together in the past, many parameters need to be checked: the fracture surface, lines running from one part to the other, letters, colors, texture, etc. When all the checked parameters fit, then the match can be determined beyond any substantial doubt. This is not always possible. Sometimes when the fit is not exact, yet a resemblance between the two parts can be seen, the expert must deal with the match in a more complex way. We can check several problems that experts might run into and the way to solve these questions.

There are three main causes for finding merely a resemblance.

Absence of material happens when a lot of material had been removed from the fracture line, during the cutting or tearing process. Using an abrasive disk to cut metallic objects, for example, removes completely all the material from the matching contour. Usually, no small details can be found in the fitting area.

In this case, the expert will rely on the general move of the cutting line showing the overall matching. The conclusion of such a match would be of a lower level than that based on an exact match of all the fine details.

Plastic deformation is a major problem in tapes and plastic bags examination. The result will be two edges that will seldom show the match immediately. The way to solve the problem in adhesive tapes involves a careful treatment of the tape. Some curing processes can be applied, such as removing the glue and straightening the edges with heat. Examination under a microscope for the basic elements of the tape, such as strings and wires (on the ‘bearer’ of the glue), might reveal some hints connecting the two deformed edges. After the edges have been cured, the conclusion can be a very strong association (Figure 2). In plastic bags, a polarized microscope might be used for the examination, revealing hidden extrusion lines running from one bag to the next one in the roll.

Match of very small fragments (‘Characteristic behavior’): When we look at a large amount of broken lines in different materials, we will notice a typical pattern of an advancing fracture line. The nature of such ‘characteristic behavior’ is

deeply dependent on the internal structure of every material. When the examined fragment is very small, this 'characteristic behavior' might confuse the expert seeking uniqueness and mislead him to a false individualization decision. The expert concluding a 'positive identification' must be aware of this phenomenon and state a conclusive result only after checking a large database of broken lines, making sure that the match is not based on the characteristic behavior of the material. The expert must be aware of this characteristic behavior, and he must assess the likelihood of finding by random chance another piece that will show very similar (or visually indistinguishable) characteristics.

Mathematical and Statistical Evaluation

Physical match is intuitively understood by any layperson; however, the concept raises serious scientific problems. The *Daubert* ruling asks, among other criteria, that the forensic expert estimate the 'potential or known error rate.' The question 'how many pieces could match, to some degree of certainty, the questioned piece' must be answered in a meaningful way.

In order to find if the match established is truly (for all practical purposes) unique, or if the alleged match may appear in other samples, and therefore is not unique – a large database for any checked material must be obtained and some mathematical calculations must be performed. It is also understood that once a numerical and statistical evaluation is involved in the physical match examination, the results will be given in a probabilistic way and not in the old conclusive statement 'these parts were (definitely) one part in the past.' (See the section 'identification/individualization' in this encyclopedia).

The way to estimate the probability of reproducing the same contour, or breakage surface, is to build a large database of similar broken (or torn) pieces. For every material, a new database must be created. Each material behaves differently during tearing or breaking, depending on its internal structure and the strength of the material. Once there will be a large collection of tearing information from many materials, a compared material will be categorized to the appropriate existing database and will be compared accordingly. For a new material, a complete array of database and graphs will have to be built, as described below. Therefore, a separate database must be created for each material in order to characterize the strength of a match.

Preparation of the database is composed of two stages: a physical component of preparing the broken pieces and a computerized, mathematical component of digitizing the images and a method or measurement to characterize the strength of the match. For the physical part, a material as close to the original as possible should be chosen. The material should be the same in measurements of thickness, age, and all the variables that the experimenter can include in order to eliminate (or reduce) the difference between the experimented materials and the tested parts subjected to examination.

To establish the statistics, all the results (both true matches and false matches) are collected, counted, and displayed using

a graph. Then the error rate is calculated using the proportion of all erroneous results and the correct matches.

Conducting thousands of comparisons manually takes so much time that it is unlikely that someone will conduct these experiments and get the statistics at the end. Therefore, a computer program that is able to perform the matches on a digital representation of the pieces is essential. Such a program requires a way to digitally represent and measure the physical characteristics of the objects.

This can be done using a scanner and a good computerized procedure to separate the breakage area from the background. The end product of this process is a reliable and reproducible digitized contour, which is the basis for computerized comparisons.

When we think about a 'match,' we usually refer to the two-dimensional fracture line; moving to a three-dimensional fracture surface adds even more information. To illustrate, if a theoretical two-dimensional material shows a good resemblance, a three-dimensional material can be viewed as several layers one on top of another. Using this concept, a 1 mm piece is composed of ten 0.1 mm layers, thus increasing the information content of the match by tenfold. This increase in the amount of data may create scanning and algorithmic problems; however, it explains why even a small area of matching surfaces can produce such convincing and powerful evidence.

On 'Identification' and 'Degree of Certainty'

In an experimental set of torn or broken objects, the experimenter, who has knowledge of the true status of each match, can classify all matches into 'correct' matches and 'false' matches. Testing many such matches will enable the collection and presentation of the matching statistics.

First, we must understand how computer comparisons are made. (Apparently, there are several methods; here, we demonstrate one of them).

Measuring the degree of resemblance or identity between two curved lines using a computer, one has to define a distance function between the two digital representations of the lines. Ideally, the distance between similar curves should be small and identical shapes should have a zero distance.

If the two lines (two opposite rims of the broken object, for example) are similar in shape then the distance between them will be close to zero (but not strictly zero as there is always some added noise due to material loss during breakage and because of the scanning and digitization processes).

What we shall see with very similar lines is this:

If the two lines are not identical or similar, there will not be a complete match, and therefore, we shall see something like the following:

The distance between the lines will not be close to zero, but there will be a positive number that we shall call 'matching error value.' The greater this value, the less likely that the two lines came from the same broken or torn object.

Having enough samples, we assemble the matched pairs into two classes. Those that are known to be correct, according to the predetermined examination done by the expert, compose the 'correct' class. All the other results are classified as 'noncorrect.' For each class, we create a histogram of the distance or 'matching error value' to show how many times we had a specific distance in our database. The two histograms are then presented on the same graph. On the left side, we see the histogram of the 'correct' matches, which generally has low matching errors; on the right side, we find the histogram of the noncorrect, or 'false' results, with larger matching errors. The example given here is artificial and shows two histograms that are separable, that is, the classes of matches and non-matches did not overlap (Figure 5).

This is of course the ideal situation that is seldom encountered. In reality, some 'right' results seem suspicious and have larger values, and some 'false' results look almost true and have smaller values. Therefore, the two curves usually overlap and look more like this (Figure 6).

Now, we can use the graph with its two (possibly overlapping) histograms to classify a new example. This is done by taking two new shapes and using the matching procedure to find their distance (or matching error). Given this number, we can try to classify the pair as a match or as a nonmatch. But to classify means to decide on a specific threshold – a number that will be used as a separation criterion. Any matching value below this number will be classified as a match, and values above this criterion will be classified as nonmatches. As the histograms (usually) overlap, our classification may be wrong.

Therefore, we find four types of classifications: If the two shapes are classified as a match, this decision may be either right (hit) or wrong (miss), that is, an erroneous classification as a nonmatch (Figure 7).

Similarly, if the pair is classified as a nonmatch, this classification too can be either right (correct reject) or wrong (false alarm), that is, an erroneous classification as a correct match (Figure 8).

Each of these four types of classifications has a probability of occurrence that can be estimated using the histograms (distributions) of the two populations, the correct matches and the nonmatches. The degree of overlap between the two populations will be determined by the discriminability of the features that are selected to characterize the match.

The probability of having these four types of classifications depends on the histograms, based on the experiments, and the location of the threshold – the 'criterion' that is used to

Figure 5 The histograms of separable match and nonmatch results: on the left side, we see the histogram of the 'correct' matches, which generally has low matching errors; on the right side, we find the histogram of the 'false' results, with larger matching errors.

Figure 6 A more realistic histogram: the two curves overlap, creating a 'gray' zone in the middle that belongs to the two histograms at the same time.

Figure 7 Two possible results for a declared match: right (hit) or wrong (miss).

Figure 8 Two possible results for a declared nonmatch: right (correct reject) or wrong (false alarm).

separate the two populations. This criterion is determined by the user according to the size of errors in the classification. If a 'false alarm' is unacceptable (for example – the convict will be executed) – the criterion shall be moved to the left edge of the nonmatches; hence, no erroneous answers will be given, but a lot of correct answers will be reported as nonmatches as well. On the other hand, if we do not want to lose any positive results – the criterion shall be moved to the right edge of the 'correct' matched' histogram. In this situation, all the correct matches will be given – but some nonmatches will be also included as 'correct' answers. Finding the balance between false acceptance and false rejection errors is a well-known and common phenomenon in any field involving decisions. The balance is usually mitigated and decided by cost-benefit and risk management strategies.

To illustrate the procedure, let us think about comparing the contours of two broken surfaces (3 cm in length), resulting from breakage of a vehicle's plastic signal lamp. In the process of breaking, small fragments of the plastic fall and the two edges of the break do not match exactly, leaving a small gap. But searching the database will probably reveal that for such a length of fracture line and in this material, the chances for another, similar fracture line has a low probability. The expert takes the numbers (the matching error value for the two fragments) and decides to call it a match. The conclusion will be phrased: 'to the best of my knowledge, and based on my search in the computerized database, I conclude that there is a very high probability that the two pieces of plastic were one part. The counter proposition that a random piece is involved has a very low probability and for any practical purpose is unrealistic.'

Summary

Physical match is undoubtedly very strong evidence, often giving conclusive discriminative results. In many cases, the match between two or more objects can strongly aid the jury in determining the innocence or guilt of the suspect. In this article, we have shown several examples in which a physical match was critical to the outcome of the investigation. The scientific process that strengthens the expert's conclusion exists, and the 'potential error rate' can be shown.

Glossary

Class characteristics Measureable features of a tool which indicate a restricted group source. They are design features of a tool and are therefore determined before manufacture. Such features include size, profile of the tool, the type of mark to be expected by use of the tool, and, sometimes, the direction of travel. Specific examples of class characteristics include width of a screwdriver blade, the jaw width along with the number and spacing of serrated teeth on the jaws of a pipe wrench, and whether a cut is produced by two blades passing over each other such as the case with scissors or two blades cutting and pinching an object such as when bolt cutters are used. Class characteristics are useful because similar class characteristics between a tool and toolmark suggest a possibility that the tool was used to create the toolmark, whereas different class characteristics will exclude that same possibility.

Exclusion Generally reported when there are significant differences in observed class characteristics or significant differences in individual characteristics that cannot be attributed to change of the tool surface over a period of time.

Identification Generally reported when class characteristics agree and there is sufficient correspondence of individual characteristics that exceeds that correspondence observed between toolmarks known to have been made by different tools and is consistent with that expected from toolmarks known to have been produced by the same tool. It is important to understand that identification is not to imply individualization. Rather, identification is a practical identity such that the likelihood another tool could have produced such a combination of individual characteristics is so remote that for all practical purposes that likelihood can be ignored.

Inconclusive Generally reported when class characteristics agree but there is insufficient similarity of individual characteristics to render a conclusion of identification or insufficient differences of individual characteristics to render a conclusion of exclusion.

Individual characteristics Those features produced by the random imperfections and irregularities of tool surfaces against an object. These imperfections and irregularities are produced incidental to manufacture meaning that they are not intended by the manufacturer. They can be microscopic or large, such as when a portion of the tool surface breaks. The combination of such characteristics on a tool surface are considered unique to a particular tool and can be used to

distinguish that tool from others having similar class characteristics.

Subclass characteristics Discernible surface features of an object that are more restrictive than class characteristics in that they are produced incidental to manufacture, represent a smaller group source or subset of the class to which they belong, and can arise from a source that changes over time. In appearance, subclass characteristics can mimic individual characteristics. However, since subclass characteristics can be present on an undefined number of tools within a particular class of tools, subclass characteristics cannot be used to distinguish a particular tool from others having similar class characteristics. Since the appearance can mimic that of individual characteristics, it is important to distinguish between individual and subclass characteristics before rendering a conclusion of identification of a toolmark as having been produced by a particular tool.

Substrate The material into which a toolmark is produced, whether it is an evidence toolmark or a test mark produced by a known tool.

Tool Defined as an implement that is designed to gain a mechanical advantage. It is also commonly thought of as being the harder of two objects that, when brought into forcible contact, will produce a mark on the softer object.

Toolmark Defined as a mark produced by a tool when that tool is brought into forcible contact with a surface against which the harder tool is used. In general, there are two types of toolmarks that can be produced, striated, and impressed. It is possible that a single tool can leave both types of toolmarks when used against an object. A *striated* toolmark is produced when a tool is placed against an object and, with applied pressure, is moved across the surface of that object creating a mark that appears as a series of fine scratches. Examples of these would include the use of a knife to cut an object, a crowbar used to pry an object open, and the use of wire cutters to cut wire. An *impressed* toolmark is produced when a tool is placed against an object and, with applied pressure, is pressed into the object leaving a full or partial negative impression of the portion of the tool that was used. They may be referred to as compression marks. Examples of these marks would include a punch used to impress a number or letter or symbol into an object and a crimping tool used to crimp electrical connectors. Toolmarks are assessed for at least two and sometimes three different features: class characteristics, individual characteristics, and subclass characteristics.

Introduction

Toolmark examinations are part of the comparative examination disciplines within the field of forensic science. It is a rather broad discipline which commonly focuses on the examination of toolmarks as evidence from crime scenes in an effort to determine the type of tool that may have been involved as well as the comparison of those toolmarks with test marks produced by recovered tools. Toolmark examination is based on the general premise that no two tools will produce sufficiently similar toolmarks, thus enabling a trained examiner to determine and possibly identify a toolmark to the tool by which it was produced.

The types of cases that may be encountered by a toolmark examiner is quite diverse including residential and business burglaries to crimes in which explosive devices have been used to create mass destruction or death. Though complex in terms of needed skill of examiners and the large number of potential tool–substrate combinations, toolmark examinations can provide investigators with valuable information not only in terms of identifying possible tools that may have been used but also whether or not a particular tool can be linked to toolmarks from the crime scene.

Definitions

Tool is defined as an implement that is designed to gain a mechanical advantage. It is also commonly thought of as being the harder of two objects that, when brought into forcible contact, will produce a mark on the softer object.

Toolmark is defined as a mark produced by a tool when that tool is brought into forcible contact with a surface against which the harder tool is used. In general, there are two types of toolmarks that can be produced, striated, and impressed. It is possible that a single tool can leave both types of toolmarks when used against an object.

A striated toolmark is produced when a tool is placed against an object and, with applied pressure, is moved across the surface of that object creating a mark that appears as a series of fine scratches. Examples of these would include the use of a knife to cut an object, a crowbar used to pry an object open, and the use of wire cutters to cut wire.

An impressed toolmark is produced when a tool is placed against an object and, with applied pressure, is pressed into the object leaving a full or partial negative impression of the portion of the tool that was used. They may be referred to as compression marks. Examples of these marks would include a punch used to impress a number or letter or symbol into an object and a crimping tool used to crimp electrical connectors.

Substrate is the material into which a toolmark is produced, whether it is an evidence toolmark or a test mark produced by a known tool.

Toolmarks are assessed for at least two and sometimes three different features: class characteristics, individual characteristics, and subclass characteristics.

Class characteristics are measureable features of a tool which indicate a restricted group source. They are design features of a tool and are therefore determined before

manufacture. Such features include size, profile of the tool, the type of mark to be expected by use of the tool, and, sometimes, the direction of travel. Specific examples of class characteristics include width of a screwdriver blade, the jaw width along with the number and spacing of serrated teeth on the jaws of a pipe wrench, and whether a cut is produced by two blades passing over each other such as the case with scissors or two blades cutting and pinching an object such as when bolt cutters are used. Class characteristics are useful because similar class characteristics between a tool and toolmark suggest a possibility that the tool was used to create the toolmark, whereas different class characteristics will exclude that same possibility.

Individual characteristics are those features produced by the random imperfections and irregularities of tool surfaces against an object. These imperfections and irregularities are produced incidental to manufacture meaning that they are not intended by the manufacturer. They can be microscopic or large, such as when a portion of the tool surface breaks. The combination of such characteristics on a tool surface is considered unique to a particular tool and can be used to distinguish that tool from others having similar class characteristics.

Subclass characteristics are discernible surface features of an object that are more restrictive than class characteristics in that they are produced incidental to manufacture, represent a smaller group source or subset of the class to which they belong, and can arise from a source that changes over time. In appearance, subclass characteristics can mimic individual characteristics. However, since subclass characteristics can be present on an undefined number of tools within a particular class of tools, subclass characteristics cannot be used to distinguish a particular tool from others having similar class characteristics. Since the appearance can mimic that of individual characteristics, it is important to distinguish between individual and subclass characteristics before rendering a conclusion of identification of a toolmark as having been produced by a particular tool.

When comparing two toolmarks, an examiner can offer findings ranging from exclusion to identification.

Exclusion will generally be reported when there are significant differences in observed class characteristics or significant differences in individual characteristics that cannot be attributed to change of the tool surface over a period of time.

Identification will generally be reported when class characteristics agree and there is sufficient correspondence of individual characteristics that exceeds that correspondence observed between toolmarks known to have been made by different tools and is consistent with that expected from toolmarks known to have been produced by the same tool. It is important to understand that identification is not to imply individualization. Rather, identification is a practical identity such that the likelihood of another tool could have produced such a combination of individual characteristics is so remote that for all practical purposes that likelihood can be ignored.

Inconclusive will generally be reported when class characteristics agree but there is insufficient similarity of individual characteristics to render a conclusion of identification or insufficient differences of individual characteristics to render a conclusion of exclusion.

Brief History of Toolmark Identification Applied to Forensic Science

Though the primary focus of historical treatment has been on firearm identification which is considered a subdiscipline of toolmark identification, toolmark identification does have a significant history in the United States with publications devoted to its application in forensic science dating back to the early twentieth century.

Among those, early publications include Souder discussing not only firearm identification, but also the identification of typewriter characters in a publication of the United States Department of Commerce in 1929. One year later, in the *American Journal of Police Science*, May discussed toolmark identification and, more specifically, the identification of a knife to cut branches at the scene of a sexual assault. Reviewed by the Washington state Supreme Court, it was clear that the work performed by the examiner, which included photo documentation, was very compelling.

Since that time, casework and research, often motivated by casework, has included a number of tools such as axes, screwdrivers, bolt cutters, slip joint pliers, knives, staplers, chisels, and glass cutters. While the tools and actions of tools varied, the underlying premise of toolmark identification, that tools produce sufficiently unique marks such that a tool can be identified to the tool by which it was produced, did not vary. The limitation of this earlier research was that comparisons of toolmarks were conducted manually and, as a result, the population sets were small.

Currently, research has been focused on defining and quantifying the similarity of toolmarks produced by the same tool and differences of toolmarks produced by different tools. This research has included consecutively manufactured tools which represent a worst-case scenario in that if any tool surfaces should be similar, it should be those manufactured in close sequence. In addition, modern research has included more automated instrumental and computer-based methodology, which not only allows for larger population sets to be evaluated but also, at least theoretically, with less subjectivity than the individual examiner-based studies of earlier years. These studies have continued to demonstrate not only the validity of the basic premise of toolmark identification but also that the trained human eye

can correctly differentiate among toolmarks that computer-based methodology has difficulty discriminating.

Application of Toolmark Identification in Forensic Science

In general, evidence suspected of bearing toolmarks will be submitted to a laboratory often in conjunction with tools suspected of being used on the evidence to produce the toolmarks. In an effort to provide investigative information, an examiner will evaluate and assess the toolmarks that are present and, in the absence of a tool, possibly provide the investigator with various tool types that could have produced the toolmarks. If tools have been submitted, then an examiner can examine the tools and, by producing test marks with the tools, perform a microscopic comparison with the toolmarks in an effort to determine whether or not the submitted tools were responsible for producing the evidence toolmarks.

An examination typically begins with an assessment of toolmarks observed on pieces of evidence. At times, this can be relatively straightforward such as when there is a single piece of evidence potentially bearing toolmarks. The complexity will rise, however, as the number of pieces of evidence increases such as to be expected in bombing case in which a pipe bomb explodes into multiple fragments and each fragment has to be examined for toolmarks which could be masked by blast damage.

When assessing evidence for toolmarks, the examiner will typically record the following features of a toolmark: tool profile as represented in the toolmark, dimensions, location, and suitability for comparison and identification. Such features are important because in the absence of a tool, much can be learned about the tool that produced the toolmark. For example, [Figures 1–3](#) illustrate three different types of cuts in wire and, based on profile, can be linked to a specific type of tool and tool action. [Figure 4](#) illustrates the information that can be gleaned from toolmarks produced by a tool on a piece of galvanized pipe.

When assessing toolmarks for suitability for comparison and identification, it is important to remember that a single tool can produce both impressed and striated toolmarks.

Figure 1 (a) A single-edged cutter which produces a shearing type mark as illustrated in (b) where the cross-section shows a continuous cut through the wire.

Figure 2 (a) A single-edged cutter with anvil which produces a toolmark as depicted in (b) where the cross-section shows the shearing action of the blade and the impressed flat of the anvil which supports the wire as it is cut. (c) illustrates the striated tool marks caused by the passing of the blade through the wire, whereas (d) illustrates the impressed tool marks caused by the flat of the anvil (which happens to have striated toolmarks on the surface).

Figure 3 (a) The rear of a double-edged cutter referred to as a side cutter. Such a double-bladed cutting action produces a profile such as that depicted in (b). The blades each pass through the wire and come together at which point the metal is 'pinched' causing it to break at this point.

Figure 5 illustrates the presence of both types of toolmarks, striated toolmarks along the sides of the cut, and impressed toolmarks along the base of the cut. Depending on the hardness of the substrate being cut, the impressed toolmarks may prove to be more useful and reproducible than the striated toolmarks.

After assessing the toolmarks, or quite possibly as an aid to examine and evaluate toolmarks on large, more cumbersome

objects, the toolmarks may be cast to allow for comparison using a comparison microscope. While this is not necessarily done for all toolmarks, it does help to facilitate comparisons both in terms of being able to more easily manipulate specimens under the comparison microscope and reducing glare and other visibility concerns with the substrate.

Based on the assessment of the toolmarks present on the various pieces of evidence, the examiner will then evaluate

submitted tools to determine whether they may have been used to produce the observed toolmarks. It is at this point that tools may be outright excluded if the class characteristics on the tools are different than those represented by the toolmarks.

Figure 4 A cast of two serrated teeth impressions on a galvanized pipe. Using the scale which is divided into 1/64 in. increments, the jaw width is determined to be approximately 15/64 inch and the teeth spacing determined to be 5/64 in. This significantly narrows the possible tools that could have produced the mark.

For those tools that remain a possibility because of similar class characteristics, an examiner will evaluate the tool for the potential of subclass characteristics that might be reproduced in toolmarks made by the tool. To determine this, the examiner will examine the tool working surface and assess how it was finished because it is the finishing process that will influence the presence of subclass characteristics on the tool working surface. As an example, if the tool surface was broached without further finishing, then there is a potential for subclass characteristics to be present, potentially limiting the usefulness of those toolmarks for identification. If the tool surface was ground, the potential for subclass characteristics is greatly diminished. Once the method of finishing is determined, the examiner will then evaluate the action of the tool against the substrate. If the tool surface has subclass characteristics and the tool is impressed into the substrate or used against the substrate in a manner that is parallel to the axis of the subclass characteristics, then there is a possibility that they will be transferred into the toolmark. Otherwise, even if subclass characteristics are present they will likely not be a factor. **Figure 6** depicts an example of subclass characteristics present on two different tools. Because of the action of the tool, these subclass characteristics do not have an impact on the comparative examinations and thus are not a factor.

In addition to determining the potential for subclass characteristics, the examiner will examine the tool for any trace evidence that may be of value. Such evidence could be

Figure 5 (a) Represents one of the cutting blades of a bolt cutter, the very edge of which is flat. As a double-edged cutting tool, the blades will cut through the substrate (wire in this case) until the blade edges come together 'pinching' the substrate between the flat edges causing the wire to break leaving the profile depicted in (b). (c) The striated toolmarks caused by the cutting action leading into the 'pinched' flat portion of the cut wire, which has impressed toolmarks present on the surface.

transferred from the substrate against which the tool was used. Examples include copper residue on wire cutter blades used to cut copper wire and flakes of galvanized metal in the serrated teeth of a pipe wrench. Not only can this trace evidence be helpful in linking the tool to the substrate but the location of the trace evidence on the tool can be useful in determining which portion of the tool may have been used. In this way, the examiner can initially target test marks in this area of the tool. **Figure 7** depicts lead residues on a cutting blade of a multi-function wire tool.

After evaluating the tool, the substrate against which the tool is suspected as having been used and the character of any evidence toolmarks, the examiner will prepare a series of test marks to compare with the evidence toolmarks. In doing so, there are several things the examiner needs to be mindful of including angle of application of tool with the substrate, the type and hardness of the substrate, and potential damage and change of the tool surface during the preparation of test marks.

For striated toolmarks, such as a screwdriver blade dragged across a piece of metal, the angle of application is very important. The same blade, depending on angle, can produce toolmarks with a different appearance. In some instances, the tool and substrate will limit this angle of application but it is an important consideration nonetheless.

The type and hardness of the substrate is a chief consideration and has to be evaluated along with the potential damage and change of the tool surface during the preparation of test marks. The character and features of toolmarks are dependent not only on the tool but also on the substrate. The same tool working surface used against different substrates can produce

toolmarks that have significant dissimilarities. For this reason, examiners typically will use test materials similar to the substrate on which evidence toolmarks to be examined are present. However, depending on the hardness of such substrates, examiners will generally produce preliminary tests in softer substrates such as lead to avoid altering the tool working surface as much as possible and then gradually use substrates of increasing hardness if necessary. It is not uncommon for successful comparative examinations to take place between test marks produced in soft lead and evidence toolmarks on galvanized metal pipe for example.

Once test marks are produced, they can be compared directly with the evidence toolmarks or, alternatively, they can be compared using casts. This is done on a comparison microscope using oblique lighting with the examiner comparing the patterns of individual marks that are present within the toolmark. If there is sufficient similarity exceeding that which is to be expected from toolmarks produced by different tools and similar to that expected from toolmarks produced by the same tool, then a trained examiner can offer an opinion of identification (see **Figure 8(a)**). Other options include exclusion when class characteristics are different (see **Figure 8(b)**) or there are sufficient differences in individual characteristics that cannot be explained by tool wear or abuse and inconclusive when there is insufficient data to render a conclusion of either identification or exclusion.

Important Considerations

Recovery of toolmark evidence is critical to the success of any later examinations that will be done. Ideally, the item in which the toolmark exists will be collected from the crime scene. Before collection, the location of collected evidence items should be documented thoroughly. The items can then be packaged according to policy either as separate pieces, or, in the case of bomb debris from a blast site, possibly by quadrant. Submission to a laboratory is needed as quickly as possible because deterioration is possible due to rusting or other environmental factors.

If the item(s) in which the toolmark evidence is present are not capable of being collected, then casts of the toolmark(s) should be prepared for submission to a laboratory for later examination. The item itself should be documented thoroughly as well as the specific location(s) of the toolmark(s) on that item. An example would be a series of pry marks on a

Figure 6 This figure depicts subclass characteristics present on the underside of an extractor hook. Based on the action of an extracting tool such as this, these marks are not produced on the substrate and will not influence the comparative examination in any way.

Figure 7 This figure represents sufficient correspondence of striated toolmarks supporting that the two toolmarks were produced by the same tool working surface.

window sill. Not only can a photograph be taken showing the toolmarks present with a scale but also the distance from a chosen edge of the sill for each toolmark can be recorded. These separate toolmarks should be given separate designations and then cast with a silicone casting material which is capable of replicating the fine microscopic detail of the toolmark. The casts should be allowed time to dry, labeled, and

Figure 8 This figure is of two casts with the cast of evidence toolmarks on the left and the cast of test marks from a tool on the right. The toolmarks are of the edges of serrated teeth from a gripping tool, in this case a pipe wrench. Based on the differences in teeth spacing depicted in the two casts, the tool working surface that produced the test marks is excluded as the surface that produced the evidence toolmarks.

then inspected before leaving the scene. Air bubbles will significantly hinder any later comparisons and can be avoided by carefully pressing the casting material into the toolmark using a wooden spatula thereby forcing out the air bubbles.

Suspect tools should be collected as quickly as possible because if they are used again, the tool working surface may be sufficiently changed so that it will not be possible to identify that tool as having made a previously produced toolmark when in fact it did. If evidence is recovered from a scene without tools, it is best to have the toolmark evidence evaluated as expediently as possible by a laboratory to at least assess and determine the potential tools that may have been involved. This will aid in the investigation as well as the preparation of any necessary search warrants for recovery of tools. When collected, tools should be carefully packaged so that the tool working surfaces, such as the blades on bolt cutters, are protected from potential damage in evidence handling as well as loss of potential trace evidence.

With respect to a conclusion of identity, in which an examiner concludes that two toolmarks were produced by the same tool, it is important to remember that it is a conclusion of 'practical' and not absolute identity. Without having examined every other tool capable of producing the toolmarks, it is not possible for an examiner to state that two toolmarks were produced by the same tool to the absolute exclusion of all other tools. The AFTE Theory of Identification, a consensus statement prepared by the Association of Firearm and Toolmark Examiners, states that identification of a tool as having made a toolmark is such that the likelihood of another tool producing that toolmark is so remote that for all practical purposes it can be ignored.

Figure 9 (a) Depicts the cutting blades of side cutters and (b) a piece of wire. Test cuts were made using the side cutters in the wire and the profile of the cut is depicted in (c). This profile is different than the profile on one evidence toolmark (d) and, therefore, it was concluded that the tool did not produce this particular evidence toolmark. The test cut was compared with other submitted evidence toolmarks and as illustrated in (e) and (f), there was sufficient correspondence of individual toolmarks to conclude that the tool did produce the other submitted toolmarks.

Casework Examples

The first example is that of side cutters compared with toolmarks present on cut pieces of wire. In this particular example, depicted in [Figure 9](#), the submitted tool could be excluded as the source of one of the evidence toolmarks but identified as the source of other, recovered evidence toolmarks.

The second example is that of slip joint pliers compared with toolmarks on a piece of copper pipe elbow. In this particular example, depicted in [Figure 10](#), the pipe elbow has striated toolmarks caused by the serrated teeth of a gripping tool slipping or dragging around the circumference of the pipe elbow as the tool is turned. Examination of the submitted tool revealed the presence of copper residues on the serrated teeth of both jaws and upon the preparation of test marks and casts of the toolmarks and test marks, it was determined that the submitted pliers did produce the toolmark observed on the copper elbow.

Future of Toolmark Identification

It appears that toolmark identification will remain a physical comparative type of examination. While computerized

technology and imaging is being developed, apart from affirming the basic premise of toolmark identification that no two tools will produce the same toolmark, it has not been able to take the place of a trained examiner in terms of distinguishing between toolmarks that are more ambiguous in nature. In addition, while an examiner can compensate for the presence of subclass characteristics (if present at all) alongside individual characteristics, current technology is not capable of making that discrimination – it all appears as individual to the software.

One area that could see improvement is developing a more standard and objective criterion by which an identification is declared. Currently, the AFTE Theory of Identification states that the final conclusion of an examiner is a subjective determination based on the individual examiner's training, experience, and expertise. Validation studies and proficiency testing have demonstrated that the range of similarity at which an identification is reached is likely small among the examiner community, therefore, allowing the science of toolmark identification to be reliable. However, there is no single discreet, objective point at which all examiners will agree that an identification has been achieved. Mathematical and statistical models are being developed that might be able to assist in this quest but unless these models can be translated to data

Figure 10 (a) Depicts the copper elbow with striated toolmarks. (b) Depicts the submitted pliers and (c) illustrates the copper residues observed in the serrated teeth of the jaws. Test marks were prepared and casts made of the evidence and test toolmarks to facilitate comparison. (d) Shows a comparison of the evidence toolmarks on the left and test marks on the right, showing sufficient similarity to conclude that the submitted tool produced the evidence toolmarks.

collected during a routine comparative examination then it will remain little more than models.

Analysis, Comparison, Evaluation, and Verification (ACE-V)

L Tierney, Gaithersburg, MD, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

As viewed in many television shows such as CSI, The Mentalist, and Bones, forensic evidence has created a large impact in American society. This is due to the fact that forensic evidence has made an even larger impact on the criminal justice system. Determining the source of items, whether they may be carpet fibers, toolmarks, shoeprints, or fingerprints, has assisted law enforcement in solving many crimes. There are a great many items that can be linked to a source, helping to tell the chain of events that transpired, whether in criminal activities or everyday life. The essential component of using forensic evidence to identify a source is making a comparison between the evidence (or unknown) and a known sample of the source. One way this can be achieved is by comparing the item with a potential source using ACE-V process.

ACE-V is an acronym that stands for analysis, comparison, evaluation, and verification and is a systematic, careful approach for the examination and comparison of forensic evidence. It is used as a framework to maintain a maximum amount of objectivity and guide the forensic examiner through the comparison process in a thorough and orderly manner, requiring that all visible information be taken into account and weighed before reaching a conclusion. Several branches of forensic science follow ACE-V either formally or informally, including fingerprints, footwear/tire tracks, and questioned documents.

History and Etiology

The concept of ACE-V as a process by which some forensic practitioners compare two or more items of evidence appears to have first been introduced by Roy Huber, a questioned document examiner with the Royal Canadian Mounted Police (RCMP) in 1959. It was at this time that Huber published an article entitled 'Expert Witnesses – In Defence of Expert Witnesses in General and of Document Examiners in Particular' in *Criminal Law Quarterly* in which he laid out analysis, comparison, and evaluation as the stages used to compare and identify a person or thing. At this time, no mention of the verification stage of the process was made.

In 1962, Huber presented this same information at an International Association for Identification (IAI) Document Seminar in St. Louis, Missouri. During this presentation, he stated that the scientific method '...insists on verification as the most reliable form of proof' but did not include verification as one of the stages in the comparison process. In 1972, Huber published a reiteration of the concept of ACE with the same quote regarding verification without the addition of a verification stage in the July–August edition of the *Royal Canadian Mounted Police Gazette* in an article entitled 'The Philosophy of Identification.'

At some point in the 1970s, the Ontario Police College adopted the concept of ACE-V but only for physical evidence. David Ashbaugh (at present, renowned as a major innovator in

the field of friction ridge examination) trained at the Ontario Police College under Harold Tuthill. Tuthill believed that fingerprints did not fall under the category of physical evidence and thus ACE-V did not apply. Ashbaugh disagreed. He felt that ACE-V was relevant and began using it as a method for the examination of friction ridge impressions.

In 1979, Ashbaugh (then with the RCMP) began putting ACE-V forward as a process for the examination of friction ridge impressions. While initially ACE-V was resisted by the community, after years of Ashbaugh presenting material to support ACE-V one concept at a time, it is with friction ridge examiners that the process has been most fully fleshed out and adopted.

At about the same time when Ashbaugh was introducing friction ridge examiners to ACE-V, Michael Cassidy (also of the RCMP) wrote and published a book entitled 'Footwear Identification' in which he espoused ACE (with a reexamination and confirmation of identification work for all inexperienced examiners) as the process for comparing footwear evidence.

While ACE-V has been adopted by individual examiners or scientific working groups in several forensic sciences, including footwear identification, tire track identification, questioned documents, forensic photographic comparison, and forensic podiatry, only in the field of friction ridge identification has the adoption of the process (while not universal) been formal and widespread enough to result in numerous publications, testing, and extensive training.

The Process

Each branch of forensic science using this process has its own definition for the steps of ACE-V, but they can be summed up generally as follows:

Analysis	A thorough assessment during which the available and relevant discriminating features are assessed for class characteristics and accidental/individual characteristics (if applicable), quantity, clarity (quality), and reliability.
Comparison	Details of the unknown and known are comparatively measured for similarities and dissimilarities.
Evaluation	Similarities and dissimilarities between the unknown and known are weighed and a conclusion is reached.
Verification	A quality check during which an independent ACE examination by a second, qualified examiner is completed.

An important aspect of the analysis phase is the determination of suitability to continue on to the comparison and evaluation phases of ACE. The determination of suitability is based on the assessment of the quality and quantity of the detail present and the discriminating strength of that detail. Any evidence that is determined not to possess enough detail with

strong specificity of features will be determined to be unsuitable or not of value for comparison (or identification).

While ACE is described as a three step process and each step is followed through to its completion, the steps are not discrete and cannot be completely isolated from each other. Instead, a blending of the steps often takes place. For example, during the comparison of the unknown and known images, data regarding the similarities and/or dissimilarities between them is gathered, and the examiner begins to see support for one conclusion over another and a tentative conclusion is reached. This is particularly apparent in the case of an exclusion or elimination where there is little or no similarity between the unknown and the known.

For simplicity sake, ACE is described as a linear process, but the steps do not always follow a linear progression and steps often recur. Just as noted above that blending of the steps may occur, an examiner may reenter the analysis phase during comparison or may reenter the comparison phase during evaluation. For example, during the comparison phase as the examiner notes a dissimilarity, he may be forced to reanalyze the known or unknown to determine if a true difference exists or if an error was made during analysis.

A note should be made that successful use of the ACE-V process requires that experts have an in-depth understanding of the manufacturing processes, biological/physiological aspects, etc., which go into making the relevant impression. Without this knowledge, a full analysis cannot be completed and the appropriate weight of different characteristics utilized during the evaluation phase cannot be determined. In fact, Huber, in his 1959 publication, stated that the true value of the expert lies in his ability to conduct a 'more efficient analysis' by ignoring less valuable information and to use his 'knowledge, training, experience, and skill' to make more accurate decisions during the evaluation phase.

Quality and Quantity of Detail

The pattern evidence disciplines (fingerprints, footwear/tiretracks, firearms/toolmarks, and questioned documents), in particular, have been the subject of much criticism in regards

to quantitative thresholds for decision making. One point these criticisms miss is that the quantity of detail in an impression does not stand alone. A Galton feature or an accidental characteristic by itself is almost meaningless and cannot be given a discrete quantity on its own. The quality, reliability, and specificity of that detail also need to be considered and weighed (considerations made during the analysis phase). As an example, an unclear and thus potentially unreliable Galton feature in a friction ridge impression can certainly not be given the same weight or quantity as a very clear and reliable Galton feature. The result is a strong relationship between quality and quantity of detail, so that as the quality of the detail increases, the need for quantity of detail decreases. The inverse is true as well in that as the quality of the detail decreases, the need for quantity of detail increases.

The relationship between quality and quantity is best illustrated in [Figure 1](#), depicting John Vanderkolk's quality quantity (QQ) curve. In this illustration of the interplay between quality and quantity in reaching a conclusion of agreement or disagreement, the X- and Y-axes represent quality and quantity of detail present in the items to be compared. The right side depicts agreement and the left side depicts disagreement. The white areas above the curves represent a combination of quantity and quality of information sufficient to determine agreement or disagreement between the items compared, while the black areas below the curves represent a combination of quantity and quality of information insufficient to determine agreement or disagreement between the items compared. The gray area represents an area of doubt where the examiner will not be able to make a determination because of insufficient information observed during the examination. If this area of doubt is where an examiner remains at the conclusion of the ACE process, a determination of insufficiency (or inconclusive) must be made.

An integral part of quality/quantity relationship is the setting of tolerances by the examiner. Tolerance refers the acceptable allowance in variation in appearance of the detail present in the evidence examined. When the detail is unclear or of low quality, the examiner may allow for a higher tolerance for acceptable variations in appearance of the same detail in the

Figure 1 Quality quantity (QQ) curve. Reprinted from Vanderkol JR (2001) Levels of quality and quantity in detail. *Journal of Forensic Identification* 51 (5): 461–468.

corresponding item. When the detail is clear or of high quality, the examiner can only allow minor tolerance for acceptable variations in appearance of the same detail in the corresponding item. These tolerances are established during the analysis phase and taken into consideration during both the comparison and evaluation phases of ACE.

Testing

Testing of a process such as ACE-V is undertaken to determine if the conclusions reached using the process are accurate and reproducible. Accurate meaning that an expert using the ACE-V process can be expected to reach the correct conclusion and reproducible meaning that all experts will reach the same conclusions.

Studies that indicate in some way the accuracy and/or reproducibility of the ACE-V process appear to primarily be limited to friction ridge identification. While several studies, each with their own limitations (found in the full publications), have been conducted which give results on the accuracy and reproducibility of friction ridge comparisons, only a few specifically reference the ACE-V process.

In 2004, Glenn Langenburg published 'Pilot Study: A Statistical Analysis of the ACE-V Methodology – Analysis Stage' in the *Journal of Forensic Identification*. In this study, 24 fingerprint examiners and trainees in the state of Minnesota and 50 novices were asked to mark the minutiae (ridge endings, bifurcations, and dots) in a total of 12 latent and inked prints. The results showed that there was no statistically significant difference for the average number of minutiae marked by trainees, examiners, and certified examiners; there was a statistically significant difference in the average number of minutiae marked by experts and novices in 8 of the 10 life-sized (1:1) latent prints; experts correctly marked more minutiae than novices in the enlarged latent print; and both the experts and the novices marked more minutiae on average in the enlargement of the latent print than in the life-sized version of the same print.

In the 2006 article 'The potential (negative) influence of observational biases at the analysis stage of fingerprint individualization' published by Beatrice Schiffer and Christophe Champod in *Forensic Science International*, forensic science students were asked to mark and determine the type of minutiae in latent prints and assess the usefulness of the prints ('exploitable' or 'identifiable'). Test I was conducted in an effort to determine whether exposure to specific theoretical and practical knowledge in forensic identification would alter the number of minutiae marked. The students were given 12 latent prints to analyze – once before completing training in forensic identification and once after. Schiffer and Champod determined that after completing training, the students found more minutiae in the latents (especially in those with background noise or low contrast), and they considered nearly twice as many of the prints 'exploitable' and more than twice as many prints 'identifiable.' Test II was conducted to observe possible differences in the number of minutiae marked when a known print is presented with the latent and with differing background case information. They found that neither the presence of a known print nor the background case

information made a significant difference to the number or type of minutiae marked or to whether the prints were determined to be 'exploitable' or 'identifiable.'

In 2006, Kasey Wertheim, Glenn Langenburg, and Andre Moenssens published an article entitled 'A Report of Latent Print Examiner Accuracy during Comparison Training Exercises' in the *Journal of Forensic Identification*. While it may be safe to infer that, because the comparison exercises reported on in the main body of the article took place in the United States (where ACE-V is widely accepted and taught) not long after friction ridge identification came under heavy attack by critics, the ACE process was being taught and therefore used for the comparison exercises, the authors do not explicitly state this. Therefore, we will focus on the report of the 'follow-up experiment' in which the authors state that the verification stage of ACE-V was tested. For this portion of the study, the authors prepared verification packets each containing two errors for 25 participants. Participants were given the conclusions of previous students and were then asked to indicate whether they agreed or disagreed with the answers. Of the 50 errors present, 49 were detected by the participants with the one error that was not detected being missed by a trainee with less than 1 year of experience, who was not yet performing unsupervised casework. This shows that verification as a quality assurance measure in the ACE-V process is effective for catching erroneous identifications. The authors also noted that not all of the correct identification answers given by previous students were agreed upon by the participants. In fact, nine of the participants with more than 1 year of experience disagreed with at least one of the correct identifications. While the exact reason for their 'disagreement' was not noted on participant worksheets, the authors surmised that examiners serving in the quality assurance role as verifier 'assume a more critical and conservative opinion. . .' The authors also suggest that because the verifiers were not just willing to just go along with all of the previous students' answers, criticism that the verification stage of the ACE-V is simply 'ratification' was not supported by the observations made in the experiment.

In the 2009 'Testing for Potential Contextual Bias Effects During the Verification Stage of the ACE-V Methodology when Conducting Fingerprint Comparisons' by Glenn Langenburg, Christophe Champod, and Pat Wertheim published in the *Journal of Forensic Sciences*, an experiment involving 43 fingerprint experts and 86 novices and the effects of contextual bias was conducted. The experts and novices (tested separately) were divided into three groups, each exposed to differing levels of contextual bias. Each group was given a set of 6 side-by-side comparisons of an unknown fingerprint and a known fingerprint and asked to provide their conclusions. The control groups were given no contextual information, the low-bias groups were provided with the conclusions of a 'latent print examiner trained to competency,' and the high-bias groups were provided with the conclusions of a 'latent print examiner trained to competency' but were also told, in person, by an internationally known latent print expert, that the conclusions were his. The results showed that the effect of contextual bias was stronger for the novice groups than for the experts. In fact, the results of the low- and high-bias groups showed that the experts were more susceptible to contextual bias toward an inconclusive result than toward identification results; that

they were more likely to provide definitive (identification or exclusion) conclusions and thus make fewer errors; and that the high-bias group was no more swayed by the opinion of an internationally known expert than an anonymous examiner trained to competency.

The 2009 article 'A Performance Study of the ACE-V Process: A Pilot Study to Measure the Accuracy, Precision, Reproducibility, Repeatability, and Biasability of Conclusions Resulting from the ACE-V Process' written by Glenn Langenburg and published in the *Journal of Forensic Identification* reports the results of testing of the ACE and ACE-V processes. For this experiment, six fingerprint experts participated in three phases of testing: Phase 1, which tested ACE; Phase 2, which tested ACE-V; and Phase 3, which involved re-presenting errors. In Phase 1, each expert was given 60 latent prints and eight known exemplars and asked to compare the prints using the ACE. Allowable conclusions were identification, exclusion, inconclusive, and no value. The experts reached 100% consensus on 43 of the 60 latent prints (72%). One of the latent prints resulted in four experts correctly making an identification and two experts making erroneous exclusions – this is explained by the author as being due to the mistaken inclusion of an image reversal (none of the participants were aware that an image reversal could be in the pool of latents). The remaining latents had mixed results in which some experts reached the correct definitive conclusion (identification or exclusion) and some experts felt that there was a lack of sufficiency in information (leading to an inconclusive determination) or that the latent was of no value for comparison.

In Phase 2, each of the six experts performed 30 ACE examinations and then passed his conclusions on to a second expert for verification, resulting in a total of 60 trials each. Before passing his conclusions on, the initial examiner was asked to change at least one of his responses to an erroneous identification (a close nonmatch). A total of nine erroneous identifications were passed on to verifiers and the verifiers detected all nine. In addition, a total of 6 false negatives were passed on to the verifiers and the verifiers detected none of them.

Phase 3 tested the repeatability of the comparison conclusions by re-presenting the errors made by the experts in phases 1 and 2 to those who made them to determine whether the individual would maintain the error. In the 10 re-presentations of errors, all three of the false positives were corrected by the examiner and four of the seven false negatives were also corrected.

Forensic Disciplines that Have not Adopted ACE-V

While ACE-V is outlined as a comparison process in publications for several different forensic disciplines, these disciplines have not necessarily adopted the acronym ACE-V or the terms analysis, comparison, evaluation, and verification as a whole.

According to members of SWGGUN (the Scientific Working Group for Firearms and Toolmarks), the traditional comparison method in firearms and toolmarks identification is pattern matching. The four-step process involves: (1) Evaluation – in which evidence is examined to determine if class characteristics between the two specimens are the same; (2) Comparison – in which

a side-by-side comparison is conducted; (3) Conclusion – a conclusion is reached; and (4) Verification – an independent evaluation of the conclusion by another qualified examiner. These steps, while using different terminology, are essentially the same process as ACE-V.

SWGTREAD (the Scientific Working Group for Shoeprint and Tiretread Evidence) at a recent meeting voted not to use the term 'ACE-V' in a footwear/tiretread comparison methodology document currently under development. While the group does not formally support ACE-V, they have developed a 'Guide for the Examination of Footwear and Tire Impression Evidence,' which is published on their web site. In the guide examination procedures include: Evaluating the impression evidence for quality, clarity, comparative and enhancement potential, and the presence or absence of class characteristics and Comparison with known footwear or tires. In addition, the web site offers acceptable Conclusions for the examinations. These procedures are very similar to ACE-V.

Conclusion

There are many different types of evidence that require examination, but for almost every type, a comparison must be conducted in order to relate the evidence to a specific source. For many disciplines of forensic science, this comparison is conducted using the analysis, comparison, evaluation, and verification or ACE-V process. As Huber states in his 1972 article 'Thus we find that various fields of identification work do have a common denominator, which is the reasoning process by which identifications are made.' ACE-V acts as a framework to maintain a maximum amount of objectivity and guide the forensic examiner through the comparison process in a thorough and orderly manner so that all available information can be taken into account and weighed before reaching a conclusion.

Glossary

Analysis Analysis is the first step of ACE-V; and it is the step used to determine if a print is suitable for comparison.

Applied science Application of trusted scientific theories to real-life situations.

Bias Effect that perception and/or mental processes may have on the reliability or validity of one's observations and conclusions. See also Confirmation Bias and Contextual Bias.

Blind verification The independent application of ACE to a friction ridge print by another qualified examiner who does not know the conclusion(s) of the previous examiner(s) and has limited or no knowledge of case information.

Comparison The examination of two friction ridge prints to detect similarities and differences. This is the second step of ACE-V but may require return to analysis.

Confirmation bias Seeing what one expects to see, and rationalizing any information that disagrees with a preconceived notion.

Contextual bias The possible influence on the examiner of information that is not directly related to a friction ridge print examination.

Distortion Variances in the reproduction of friction ridge arrangements of the skin caused by pressure, movement, force, contact surface, etc.

Evaluation The formulation of a conclusion based on the interpretation of all the data gathered during analysis and comparison. This is the third step of ACE-V.

Exclusion A decision by a qualified examiner that there are sufficient features in disagreement to conclude that two

areas of friction ridge prints do not originate from the same source, where source refers to the area of friction ridge skin that produced the latent print in question.

Identification (Individualization) A decision by a qualified examiner that there are sufficient features in agreement to conclude that two friction ridge prints come from the same source.

Inconclusive A decision by a qualified examiner that means a conclusive decision (identification or exclusion) could not be reached. Inconclusive means that more information is required to come to a conclusive decision. The meaning of the inconclusive decision varies based on the definition of suitability for comparison that is used by the reporting agency.

Latent print (Mark) Unintentional or uncontrolled deposition of the friction ridge arrangements of the skin onto a substrate. These are often fragmentary and may require forensic light sources, chemicals, or powders to visualize.

Level I detail Overall ridge flow and print morphology.

Level II detail Individual friction ridge paths and friction ridge events (e.g., dividing ridges, ending ridges, and dots).

Level III detail Dimensional attributes of individual friction ridges (e.g., width, ridge shapes, and pores).

Premises The knowledge that friction ridge arrangements are unique and persistent has been supported through study; therefore, the premises of uniqueness and persistency are used as a given allowing examiners to conduct friction ridge print examinations.

Quality The clarity and the discriminating strength of the data contained in a friction ridge print.

Quantity The amount of information contained in an area of a friction ridge print.

Suitability Determination that a friction ridge print contains enough quantity and quality of information to be used for comparison. Some agencies use a suitable for identification standard, while others use a suitable for

identification or exclusion standard. The terms of value and of no value are commonly used interchangeably with suitability.

Verification Independent application of analysis, comparison, and evaluation by a qualified examiner. This fourth step of ACE-V may include a peer review of the data used to reach a conclusion.

Friction Ridge Print Examination – Interpretation and the Comparative Method

The examination of friction ridge prints is a scientific endeavor that involves the application of information learned from many fields of science. A qualified examiner must have an understanding of the embryological development and biological regeneration of friction ridge skin in order to fully understand how it might appear when recorded. The understanding of the development and structure of skin gives qualified, trained examiners the ability to interpret the data left in two-dimensional (2D) recordings of the 3D surface of the skin.

Due to the pliability of the skin, features may appear slightly different in each recording, but a qualified examiner will recognize that these features will move in concert as they are locked together in their arrangement. This means that while each recording of an area of friction ridge print will appear slightly different, the examiner must be trained to recognize the limitations of the movement of the skin.

The qualified examiner must also know, by understanding the development of the skin as well as through empirical review of friction ridge prints, the discriminating strengths of different features and how the discriminating strength changes in different areas of the friction ridge skin. An understanding of pattern force development will assist the examiner in recognizing that certain areas of the skin may require more features to have the same discriminating strength as fewer features in another area. This will also be evident when examining prints, and this is why a large amount of friction ridge prints should be studied before an examiner is considered qualified to conduct friction ridge print examinations.

In order to apply this knowledge in a systematic manner and properly interpret the data available in friction ridge print examinations, examiners apply ACE-V. ACE-V stands for analysis, comparison, evaluation, and verification and is the standard process used by friction ridge print examiners.

Analysis, Comparison, Evaluation, and Verification

ACE-V is a holistic process used in comparative sciences, such as friction ridge print examinations. ACE-V is a systematic way of conducting examinations. When following ACE-V, an analyst takes into account the quality (clarity of the features and the discriminating strength of those features) and quantity

(amount of features in an area) of information present in a latent print. This quality and quantity are assessed during the analysis step.

Analysis is the information-gathering step of the ACE-V process. The prints are analyzed independently, usually beginning with the lower-quality print. Analysis serves to identify tolerance, classify and orient friction ridge prints, and reduce contamination, or bias, from information in the known print. During analysis, the expert assesses factors (distortions) that affect the appearance of the print. These factors include, but are not limited to, matrix (the substance the friction ridge print is left in, such as sweat or oil), substrate (the material the friction ridge print is left on), development medium (the chemical, forensic light source, or powder used to make a latent print visible), and pressure and movement. The three levels of detail, as detailed in [Figure 1](#), contained within a print are also assessed.

Once all of the information contained in a print has been assessed, a determination of suitability for comparison is made. Suitability is the determination that a print has an adequate quality and quantity of information. This determination is based on the assessment of the discriminating strengths of the features and their arrangement within the print. There are two approaches to determining suitability for comparison. Some agencies determine that a print is suitable for comparison if it contains sufficient reliable information in order to determine that the print can be identified to a source, given the corresponding known print. Other agencies determine that a print is suitable for comparison if the print can be excluded or identified.

Comparison begins after a determination of suitability for comparison is made. During comparison, additional information is gathered in the form of a side-by-side examination of the latent, or unknown, print and the known print to determine agreement and disagreement. An examiner is not looking for the prints to be identical but is using the information gathered in analysis to determine whether areas of agreement or differences between the friction ridge arrangements exist. To ensure that examiners are properly interpreting data, strong quality assurance measures, including thorough documentation, are essential for transparency.

Analysis and comparison are not completely distinct steps. A thorough analysis must be conducted and documented prior to beginning comparison; however, once comparison has begun, it may be necessary to reanalyze information that was interpreted differently prior to comparison. It is imperative

Figure 1 Three levels of detail.

that any new data interpretation developed after the beginning of the comparison should be documented thoroughly to ensure a proper recording of the interpretive steps of the examination.

During the evaluation phase, all the information gathered during analysis and comparison is used to generate a conclusion. The information is evaluated, and it is determined whether the prints come from different sources, the same source, or there is not sufficient information to render a conclusive decision. There are three corresponding decisions that can be reached: exclusion, identification, or inconclusive.

Exclusion is a decision made by a qualified examiner that there are sufficient features in disagreement to conclude that two areas of friction ridge impressions do not originate from the same source, where source refers to an area of friction ridge skin.

Identification (individualization) is a decision made by a qualified examiner that there are sufficient features in agreement to conclude that two friction ridge prints come from the same source. The identification of a friction ridge print to a source is the decision that the likelihood the impression was made by another (different) source is so remote that it is considered as a practical impossibility.

An inconclusive decision means that more information is required to reach a conclusive decision. The meaning of an inconclusive decision varies based on the definition of suitability for comparison that is used by the reporting agency.

If an agency is using the suitability for identification standard, then an inconclusive decision means that a latent print contains sufficient reliable information to be identified and more information is needed in the known print. This can happen if the comparable areas are not available for comparison. An example of this is if the latent print is from the tip area of the finger and this information is not available on the corresponding known print. More information is needed from the known print before an exclusion or identification decision can be made. This can also occur if the corresponding areas are recorded but are not of sufficient quality for comparison.

If an agency is using the suitability for exclusion and identification standard, then an inconclusive decision is rendered when there are features that are noted to be different, but there is not enough information to generate an exclusion decision. Alternatively, there may be some information in agreement but not enough to render an identification decision. This may include situations where more information is required in the known print.

In all cases where an inconclusive decision is rendered, regardless of the suitability standard, there is not enough information present between the prints being compared in order to generate either an exclusion or an identification decision.

Verification is the final step in the ACE-V process. In verification, another qualified examiner performs an independent analysis on and comparison and evaluation of the two prints to verify the examination of the original examiner. It is a quality measure built into the process. It is a standard practice that all identification decisions must be verified, but in other instances when verification must be performed, it should be built into the quality system of an agency. Verification of an erroneous decision is equivalent to making the erroneous decision and is treated with the same gravity.

Each step of ACE-V, as described above, involves interpretation of data. Because all the data interpretation is conducted and known only to the examiner's brain, thorough documentation is imperative.

ACE-V as an Applied Science

ACE-V is an applied process using information determined through studies previously conducted in other sciences. ACE-V is applied by a human being, so the risk of error must be mitigated through quality control measures. Verification, the quality control measure built directly into the process, is automatic for identifications but applicable to all conclusions (SWGFAST), but it should not be the only form of quality control used when conducting ACE-V.

Blind Verification

Blind verification functions as a quality control measure, testing the reproducibility of decisions made during ACE-V by limiting the bias introduced into the examinations. Blind verification is the independent application of ACE to a friction ridge print by another qualified examiner who does not know the conclusion(s) of the previous examiner(s) and has limited or no knowledge of the case information. It should be used to eliminate confirmation bias and limit contextual bias in the examinations of friction ridge prints. Blind verification may be used at any step of the ACE process where a decision is made.

Bias is a term that can be used for any number of outside influences that may affect the cognitive decision process during the examination. Two types of bias are most commonly discussed in relation to the comparative sciences – confirmation and contextual bias.

Confirmation bias, in general terms, is seeing what one expects to see, and disregarding or minimizing any information that disagrees with a preconceived notion. There is concern that this type of bias may enter friction ridge print examination during verification or any peer review because the verifying/reviewing examiner knows the conclusion of the original examiner.

Contextual bias is the potential influence exerted on the examiner by the details in the case that are not directly related to the print. Contextual bias may occur, for example, if the examiner knows specific details of the criminal activity or the investigative steps leading up to the submission of the evidence being examined.

Consultation

In any scientific endeavor, consultation may be necessary. At times, an examiner may need to consult someone with more experience, whether counted in number of years or prior exposure to a particular type of evidence, or a trusted colleague for their view of the evidence. This may occur if there are distortions affecting the appearance of a print, the surface that the print is on is unusual, or an examiner wants to ensure that he or she is interpreting the data correctly. Consultation is always encouraged, as it allows examiners to objectively discuss the information present in the friction ridge prints. Consultation should be documented, and it must not be substituted for verification. Verification must be conducted independently by a qualified examiner who has not been consulted in the examination process.

Complex Prints

At times, an examiner may determine that a print is complex. This may occur when a more in-depth analysis is needed due to the presence of distortion (i.e., extreme pressure, extreme movement, unusual matrix, and unusual development). More detailed documentation is required when examining complex prints.

Conflict Resolution

Opinions may vary from expert to expert; therefore, agencies should have a process in place to attempt to resolve these technical conflicts. It is possible to develop multiple ways to resolve conflict. Some agencies may use a discussion-based approach where the experts attempt to resolve the conflict through documented discussion, possibly in conjunction with a third-party arbiter. Other agencies may adopt policies that involve reaching a consensus through a group, and still other agencies may choose to use blind verification as a means to resolve conflict. Conflicts may occur in multiple areas throughout the ACE-V process.

The key to a conflict resolution policy is that there should also be an attempt to determine if a corrective action is appropriate through review of the data and the interpretations generated using that data.

Documentation

Documentation of friction ridge print examinations must be such that another qualified examiner can determine what examinations were conducted and can interpret the data. It may also be helpful for the documentation to make clear specifically which data were used to generate the conclusions that were reached. This transparency not only helps the courts understand which data were used and how, but also helps in any quality review process should an error occur.

All relevant information that is available to the examiner should be documented. However, the extent of detail of the documentation may be different, depending on the complexity of the examination. The print alone is not enough documentation since it provides no understanding of how a conclusion was reached. The print must be accompanied by annotations or notes. An attempt should be made to thoroughly document all steps in the process where interpretation of data occurs.

Analysis is the initial data-gathering phase and should be documented prior to comparison to avoid any contamination of the brain by information from the known print. The minimum documentation that should be required for analysis is the anatomical source (fingerprint, palm print, toe print, foot-print, impression), level I detail present (orientation, distal direction, etc.), and level II detail present. If they are known, the substrate, development medium, and preservation method (lift, photograph, etc.) should be documented as well. Other things that may need documentation could be the matrix, pressure, movement, level III detail (if reliably recorded), and any other features of the print that may affect a decision (creases, scars, etc.).

After analysis, two or more prints are compared to each other. This comparison should also be documented. A legible copy of the known exemplar (or the original known exemplar) should be kept in the case record for any future verification uses, or the exemplar should be retrievable. The known exemplar should have some form of a unique identifier tying it to the individual being compared and separating it from anyone

else. It should also be documented if the known exemplar is not suitable for comparison. Along with this documentation, any information that is used during the comparison that was not originally documented in analysis should be documented, and it should be clear what information was detected during the comparison versus what was detected during the analysis. This will provide transparency as to what data was interpreted at which phase of ACE.

Proper documentation is required in order to clearly state the conclusions reached in the evaluation phase. When documenting identifications, it must be made clear which friction ridge print has been identified. The individual identified must be documented as well as the anatomical origin (finger position, right/left palm, etc.). It must be clear which examiner reached the conclusion and when he or she reached it. An exclusion should be documented in a similar manner. It must be clear from the case file which known print was compared to which latent print and which examiner reached a conclusion and when. Documentation for an inconclusive decision should contain all the same information, who reached the conclusion, when the conclusion was reached, the known print(s) used, the latent print examined, and the anatomical area(s) compared. Due to the different possible meanings of inconclusive decision based on the type of suitability for comparison standard used, an inconclusive decision needs more documentation for transparency. It must be made clear why this examination has been deemed inconclusive. If the print was compared under the suitable for identification standard, better known prints would be required, and this should be documented. If the print was compared under the suitable for exclusion and identification standard, it must be made clear if better known prints are required for conclusive comparisons, or if there was insufficient ridge detail in agreement based on the latent print alone. This allows investigators to know if they need to retrieve more known exemplars. All conclusions must be documented before having a conclusion verified. Documentation of a verification or blind verification must include all the same information as that of the original evaluation documentation.

Consultations should also be documented for transparency. This should include which print was reviewed or discussed, what the consultation entailed, and what results were generated, along with an indication of which examiner was consulted and the date of the consultation.

Ownership of the documentation is also imperative. All documentation should be dated and initialed, signed, or the equivalent, by the individual(s) who participated in each specific activity. This documentation will allow for transparency, ownership, and peer review.

Glossary

Algorithm A step-by-step procedure for solving a problem or accomplishing some end especially by a computer.

Alias Otherwise known as.

Anthropometry Distinct measurements of the human body.

Arch A pattern type in which the friction ridges enter on one side of the impression and flow, or tend to flow, out the other side with a rise or wave in the center. Arches are subdivided into plain and tented arches.

Automated Fingerprint Identification System

(AFIS) A generic term for a fingerprint matching, storage, and retrieval system.

Classification system Alphanumeric formula of finger and palmprint patterns used as a guide for filing and searching.

Friction ridge A raised portion of the epidermis on the palmar or plantar skin, consisting of one or more connected ridge units.

Henry classification An alpha-numeric system of fingerprint classification named after Sir Edward Richard Henry used for filing, searching, and retrieving ten print records.

Identification The determination by an examiner that there is neither sufficient agreement to individualize nor sufficient disagreement to exclude.

Impression Friction ridge detail deposited on a surface.

Integrated Automated Fingerprint Identification System (IAFIS) The acronym for Integrated Automated Fingerprint Identification System, the FBI's national AFIS.

Interoperable The ability of computer hardware and software to be interchanged between manufacturers.

Joint Automated Booking System (JABS) An information sharing system and a conduit for sending standard booking data directly to the Federal Bureau of Investigation's (FBI's) IAFIS.

Known fingerprints The fingerprints of an individual, associated with a known or claimed identity, and

deliberately recorded electronically, by ink, or another medium. Also known as exemplars.

Latent print Transferred impression of friction ridge detail not readily visible. Generic term used for unintentionally deposited friction ridge detail.

Live-scan Technology used to capture fingerprints, palm prints, and descriptive information electronically.

Loop A type of pattern in which one or more friction ridges enter on either side, recurve, touch or pass an imaginary line between delta and core and flow out, or tend to flow out on the same side the friction ridges entered. Loops are subdivided into radial and ulnar loops.

Minutiae Events along a ridge path, including bifurcations, ending ridges, and dots (also known as Galton details).

Mug shot Police photograph of a suspect's face or profile.

Next generation identification (NGI) FBI's incremental replacement for IAFIS that will offer state-of-the-art biometric identification services.

Pattern type Fundamental pattern of the ridge flow: arch, loop, and whorl.

Persistence Having lasting qualities; remaining the same; nonchanging.

Proprietary Something that is used, produced, or marketed under exclusive legal right of the inventor or maker.

Recidivist A habitual criminal.

Scotland Yard Metropolitan Police Service of London, United Kingdom.

Uniqueness Very uncommon, unusual, atypical, or remarkable; a degree of distinguishing distinctiveness.

Verification The act or process of confirming.

Whorl A fingerprint pattern type that consists of one or more friction ridges that make, or tends to make, a complete circuit, with two deltas, between which, when an imaginary line is drawn, at least one recurving friction ridge within the inner pattern area is cut or touched. Whorls are subdivided into plain whorls, double loops, pocket loops, and accidental whorls.

Introduction

The root of fingerprint automation began with the concept of uniqueness and persistence of friction ridges and the ability of known fingerprints to be classified into a system in which fingerprint cards can be filed and retrieved. The invention of a classification system that was fairly easy to use and could accommodate fairly large amounts of data was a pivotal moment in the history of fingerprint automation. However, as classified fingerprint files became larger and larger, the time it took a fingerprint technician to find a specific fingerprint card became longer and longer. The solution to this time delay rested with the invention of the computer and the eventual

automation of fingerprint and palm print files. The fingerprint files were associated with the valuable information regarding those individuals. Not only did the file hold one's fingerprint impressions but also contained the descriptive information of the individual and the previous criminal activity. As one can see, the act of automating fingerprint files was a major milestone in the advancement of modern forensic science.

Brief History of Fingerprint Classification

The first instance of the scientific recognition of friction ridges dates back to the early 1800s when Professor Johannes

Evangelista Purkinje (1787–1869) wrote his thesis entitled 'A Commentary on the Physiological Examination of the Organs of Vision and the Cutaneous System' (1823). In this, Purkinje illustrated nine different types of fingerprint patterns: transverse curves, central longitudinal stria, oblique stria, oblique sinus, almond, spiral, elliptical whorl, circular whorl, and double whorl. Although Purkinje's work was purely of the anatomical nature, the delineation of classifiable patterns as the basis of a method of personal identification was born.

It was not for another 50 years that the topic of fingerprint classification was broached. In 1880, Dr. Henry Faulds, a Scottish missionary working in Japan, began his own research into fingerprint identification and classification. Faulds was crucial to the science of fingerprints in that he conducted experiments to prove that fingerprints were both unique and persistent. With this basis, he proposed that friction ridge impressions could be classified into a system and used to identify criminals. Faulds also was the first to develop a ten-digit fingerprint card to record all ten fingerprint impressions using ink. Faulds began collecting fingerprints and soon had thousands of known fingerprint cards. With these cards in hand, Faulds attempted to create a system of fingerprint classification. His system was based on assigning syllables that he constructed to each finger of the hand and then syllables to the pattern characteristics within each finger. Faulds offered to bring his classification system to Scotland Yard, but it was declined because of the fact that Scotland Yard was currently using a method of personal identification known as anthropometry (officially named Bertillonage after its inventor, Alphonse Bertillon).

Sir Francis Galton (1822–1911) became interested in the use of fingerprints when he was asked to give a lecture on personal identification. In researching the current method of the time, Bertillonage, Galton realized its inadequacy and thus initiated his research into fingerprints. Galton amassed a large collection of fingerprints (approximately 8000 sets) and began formal studies into human friction ridges. In 1892, Galton published his seminal work, *Finger Prints*, in which he established the two tenets of fingerprint identification, uniqueness, and persistence. In this groundbreaking work, Galton described how friction ridges did not flow uninterrupted but may end, split into more ridges, split and then reconnect, or connect to other ridges. These deviations are commonly referred to as minutiae, or Galton details. In this book, Galton also developed a classification method. Like Purkinje, 69 years earlier, Galton described distinct types of fingerprint patterns. While Purkinje detailed nine pattern types, Galton described only three, the arch, loop, and whorl. To this day, fingerprints are still divided into these three major classes of patterns. Galton's classification was based on analyzing the pattern of each finger impression, assigning the impression letter, and then grouping the fingers of the right hand and left hand into predetermined groups. This classification would create a string of ten letters, representing each finger of the hand in a certain order. Although this classification system was the first system to be incorporated into criminal files within an organization (Scotland Yard), it was too general of a system to handle large numbers of files and proved useless.

In Argentina, Juan Vucetich (1858–1925), the head of the Office of Identification in the Buenos Aires Police Department, read a scientific review of Galton's work with fingerprints. Like

Galton, Vucetich realized the value of fingerprint identification and began to collect the fingerprints of all those arrested by his police department. In 1891, Vucetich also realized that in order for fingerprints to be truly recognized as the foremost means of personal identification, it had to have a successful classification system. Using Galton's three-pattern classification system, Vucetich devised an alphanumeric system that added an additional pattern for a total of four (arch, internal loop, external loop, and whorl) and incorporated a secondary classification and ridge counts. His classification was expressed in the form of a ratio, with the right hand as the numerator and the left hand as the denominator. The incorporation of this additional discriminatory sorting allowed fingerprint cards to be categorized into small groups, which were easily searched. Having now created a successful classification system, in 1894, he successfully campaigned for the use of fingerprints to be the sole means of personal identification within his agency, thereby completely eliminating the use of anthropometry.

During the same time that Vucetich was creating his classification, Sir Edward Henry (1850–1931) had also realized the need for a robust method of personal identification as a district Inspector General in India. After reading Galton's *Finger Prints*, Henry instituted that the fingerprints of all prisoners in his district be recorded. He also obtained all of Galton's research materials with the intent to create a formidable classification system. Henry assigned this task to two police officers from the Calcutta Anthropometric Bureau. By 1897, the two officers, Azizul Haque and Hem Chandra Bose, using Galton's three patterns, devised a classification system that involved three separate alphanumerical classifications, the primary, secondary, and subsecondary, and was expressed as a ratio, with the even fingers calculation as the numerator and the odd fingers calculation as the denominator. The primary classification was based on the presence of whorls on the fingers, the secondary was determined by the pattern types on the right and left index fingers, and the subsecondary represented the ridge counts or ridge tracings for the remaining fingers. In 1900, the Belper Committee in England, established to determine the best method of criminal identification, recommended that the Henry classification system be the sole means of criminal identification. With this recommendation, the Henry classification system was adopted by the Scotland Yard as its official means of personal identification in 1901.

The classification systems discussed above could only be used for cataloging and comparing fingerprint cards containing ten fingerprint impressions. The systems were instituted to identify individuals for whom ten fingerprint images could be recorded. This certainly worked for recidivists and other known individuals. However, these systems fell short with regard to the searching of single fingerprints obtained from crime scenes, commonly known as latent prints. In these cases, investigations could only go as far as the development of potential suspects and then obtaining a full set of fingerprint impressions in order to compare with the latent print. It was this obvious limitation that led to the development of single-fingerprint classification systems.

Single-fingerprint classification systems were based on either the existing ten-print classification systems or the original. Establishing single-fingerprint files involved creating entirely new cards for each fingerprint of an individual. Each card

contained descriptive information, the written classification, and either the fingerprint image itself or a verbal description of the classification. If a latent fingerprint could be classified, it could then be searched in the single fingerprint files. The most popular single fingerprint system was developed at New Scotland Yard and was known as the Battley Single-Fingerprint System. While these files served a function that the ten print files could not offer, they added another layer of time-consuming labor and volume.

History of Criminal Identification

An individual's criminal history record associates personal identifiers to arrest and disposition data. Until the mid-1850s, this information was haphazardly recorded as notes and associated with a name, of which could easily have been an alias. As populations and the criminal element grew, it became increasingly difficult to accurately document a person's criminal record and associate descriptive data with a record in order to accurately identify recidivists. The advent of photography was a pivotal moment in the criminal justice community. Officials could now attach a photograph (the mug-shot) to a criminal history record. While the use of photographs greatly advanced the criminal justice system, it was not the be-all and end-all of criminal identification because of the fact that a criminal could easily change his/her appearance. In addition, many police departments did not institute standard operating procedures for mug shots. Historic mug shots often contained people wearing hats, women with veils, and heads tilted.

The next milestone in criminal identification was initially viewed as the first truly scientific method of criminal identification. In 1882, Alphonse Bertillon, a police clerk in Paris, France, developed a system of body measurements to be used for identification. Known as anthropometry, the system involved distinct measurements of the human body. These measurements, a total of 11, were recorded with descriptive data such as height and eye color, body deformities or marks such as scars, mug shots, and the 11 measurements. In 1894, Galton's fingerprint classification was added to the Bertillonage record of criminal identification. Not long after Bertillonage was instituted as a means of identification, the problem with anthropometry was becoming apparent in three ways. First, different officers could record different measurements of the same body parts. The difference was enough that false identifications could be made or recidivists could be missed. Second, the system did not account for growth or aging of the body. Measurements taken from an individual throughout growth and the aging process could be different enough to preclude an identification. Third, the system was proving unable to handle large amounts of data. As files grew, the time it took for the officers to search and locate a file became debilitating. As the problems with anthropometry intensified the use of a fingerprint classification system to accurately identify individuals emerged as the premier method of identification.

History of Fingerprint Automation

As agency files of classified fingerprint cards became larger and larger, the time it took to conduct a search became longer and

longer, oftentimes taking months to report back that a ten print card did or did not match an existing card in the files. In addition, departments that added single-fingerprint files compounded the man hours it took to conduct an investigation. Obviously, the timeliness and high personnel costs of ten print card searches coupled with the inefficient and inadequate single-print systems became a paramount concern for the criminal justice and forensic community.

The first attempt to automate was conducted by the Federal Bureau of Investigation (FBI) in 1934. A mere 10 years after the United States Congress created the FBI and established it as the national fingerprint repository, whereby it took possession of over 800 000 fingerprint records from the Leavenworth prison, the FBI was feeling the pains of a large repository that was time-consuming to search. Even with modifications to the Henry classification system in order to create additional subclassification groupings, the FBI's files were burgeoning and the bureau recognized the need for some type of automation. This automation came in the form of the data punch card and card-sorting machines. A data punch card is a stiff card that contains rows and columns of holes, each hole representing a piece of data. The data punch card would be encoded with descriptive information for individuals along with their fingerprint classification. Cards could later be searched with a card-sorting machine. If the machine detected a card with the same data (i.e., the desired Henry classification) then the fingerprint examiner could then manually pull that card and compare it to the submitted card from the contributor. Even though this process reduced the amount of time it took a fingerprint technician to search for a card, the FBI determined that the continued use of this automated punch card system was still not feasible for the collection of its size and abandoned the project. However, the use of the punch card systems for cataloging fingerprint files was adequate for smaller and more manageable fingerprint files, thus it was used by state and local agencies.

It was not until the 1960s that the advancement in computer technology opened the door for viable method of fingerprint automation. Computer technology had advanced to the point where the ability of computers to read and match fingerprints automatically was certainly within the realm of reality. With this in mind, agencies across the map began to initiate fingerprint automation projects.

In the late 1960s, the FBI's Identification Division initiated its Automated Identification Division System (AIDS) program and in conjunction with the National Bureau of Standards (NBS) (NBS; currently known as the National Institute of Standards and Technology (NIST)) looked into the technological requirements needed to develop special purpose computers to automate fingerprint records. The FBI and the NBS determined that in order to build an Automated Fingerprint Identification System (AFIS), new technologies would have to be developed. This involved a scanner that would be able to detect fingerprint impressions on a ten print card, software to accurately read the fingerprint impression and detect minutiae, and computer algorithms that could accurately compare the information (pattern type and minutiae location) from the scanned print with a database of known prints. With these requirements, the FBI issued a request for proposal (RFP) to the community to build the AFIS demonstration models that would address the first two milestones. The third technology was addressed by the NBS. In

the early 1970s, two additional RFPs were issued, which incorporated speed and accuracy requirements. By the mid-1970s, the FBI's AIDS program possessed five AFIS machines that were used for the digital conversion of the FBI's criminal fingerprint file. In 1979, the FBI was testing the search function of the new AFIS, and by 1983, automatic searches were routine.

While the FBI was experimenting and developing their AFIS system, numerous other agencies, national and international, started down the same path of fingerprint automation. Some agencies successfully worked on in-house computer systems (United Kingdom's Home Office), while others either experienced budgetary constraints that caused them to shut the program down or developed systems with technology that was not as applicable as that developed by the FBI. Other agencies, such as the FBI, contracted with firms to develop their own AFIS. In France, the French National Police contracted with a subsidiary of Morpho Systems (Currently Safran Morpho, Inc.) to develop an AFIS. In Japan, the National Police Agency contracted with NEC Corporation to develop their AFIS. With the success of the AFIS technology, companies began marketing their own AFISs that were based on proprietary software. As a result, many agencies were purchasing systems that were not interoperable with each other. Some agencies developed funding strategies that allowed regions to combine resources in order to purchase a single-source AFIS, thereby creating a shared network of AFIS. For example, the Western Identification Network (WIN) in the United States combines the fingerprint records of Alaska, California, Idaho, Montana, Nevada, Oregon, Utah, Washington, and Wyoming.

Key to the success of AFIS was the fact that it was based on the AFIS pattern classifications, minutiae extraction, and matching algorithms. With this new technology, the fingerprint classification systems that were previously discussed became outdated, at least for those agencies utilizing the new AFIS technology. The new AFISs had no use for the traditional classification systems. Each fingerprint on a ten print card was automatically classified by a computer algorithm into eight possible patterns: arch, whorl, right-slant loop, left-slant loop, complete scar, amputation, unable to classify, and unable to print. AFIS fingerprint classification was now based strictly on the location of extracted minutiae (bifurcations and ending ridges only) and the spatial relationships between the minutiae. As a result, the minutiae extraction algorithms created mathematical maps of each fingerprint on the card. New cards entering the system would be automatically classified into AFIS pattern classifications, and the minutiae in each fingerprint would be automatically encoded.

AFISs are composed of two subsystems: (1) known print subsystem and (2) latent subsystem. The known print subsystem achieves what the manual classification systems of the past did, identity verification. It is through this subsystem that identification queries take place. This subsystem is used for criminal identification and employment application processes. The latent subsystem incorporates additional software that facilitates the searching and matching of latent prints against a designated database. This latent aspect involves the encoding of the minutiae from the latent print in order to create a mathematical map. The mathematical map of the latent print can then be compared to the mathematical maps in the queried database. This comparison results in a list of potential

candidates, which a latent print examiner trained to competency can compare and render a conclusion.

In an effort to institute some form of standardization across multiple AFIS vendors, in the early to the mid-1990s, the NIST established standards for the transmission of fingerprint information. These standards include types of records that are sent through the live-scan technology and AFISs. Record types include information on the sending and receiving agency; descriptive and arrest information; signatures; image resolution; latent and known images; marked minutiae; and facial, scars, marks, and tattoo image transmission. Additional standards exist regarding the image quality of equipment and the image compression for transmission.

Criminal History Information Systems

The integration of computer technologies into the criminal justice community also afforded agencies the ability to automate and then eventually centralize criminal history records. Up until the 1960s, criminal record histories were paper-based and in manual files. Obviously, paper-based files were only valuable for the area covered by that particular agency. Even if the files were automated, if it was not possible for the criminal history files to be shared between agencies, then they were no better than paper-based files. If the criminal justice community was going to address multijurisdictional offenders, then a centralized system was in order. Beyond traditional criminal justice purposes, a centralized database would assist in background checks for licensing, employment suitability, and national security clearances. The push for agencies in the United States to automate their criminal records began with the passage of the Omnibus Crime Control and Safe Streets Act of 1968. The establishment of the Law Enforcement Assistance Administration provided grant money to states to develop computerized criminal history record systems. As of December 31, 2008, there were 85 836 300 automated criminal history files in the United States (Survey of State Criminal History Information Systems, 2008. SEARCH National Consortium for Justice Information and Statistics. US Department of Justice, Bureau of Justice Statistics, Published October, 2009.).

The National Crime Information Center (NCIC) was established in 1965 as the United States' centralized electronic criminal database of wanted and missing persons and stolen property. While the NCIC is maintained by and housed at the FBI's Criminal Justice Information Services (CJIS) Division of the FBI, since inception, it has operated under a shared management structure with the FBI and local, state, and other federal agencies. States, districts, and territories can access the NCIC through dedicated lines of telecommunication. The purpose of the NCIC was to create a database that could be constantly and immediately updated and searched by local, state, and federal agencies. The obvious advantages being that the agencies can conduct instant checks regarding people and property. This computerized database consists of personal records (fugitives, missing persons, and wanted individuals, etc.) and stolen property records that can be searched 24 h a day, 7 days a week.

Associated with the personal records database is the NCIC fingerprint classification. Like the Henry fingerprint classification system, the NCIC fingerprint classification was established

to assist users in tentatively identifying wanted criminals. For example, police officers can query the system with a suspect's NCIC fingerprint classification to establish if that person may be in the NCIC personal records file as a wanted person. Unlike the Henry system, the NCIC fingerprint classification system is simpler to use and understand and could be transmitted with far less error than the Henry classification. The system is alphanumeric, consists of a 20-character code in a single row, where each finger is represented by two characters, and can be converted into the Henry classification. The code starts with the right thumb and ends with left little finger. For example, a person possessing plain arches on all fingers, with the exception that both index fingers have tented arches, would have an NCIC fingerprint classification of AA TT AA AA AA AA TT AA AA AA.

The FBI created the nation's automated criminal history record information, the Interstate Identification Index (III), in 1978. The III is an index of a person's federal or state arrest record and is accessed through the NCIC. Participation in the III is voluntary. In order to participate in the III, the state, district, or territory must be authorized by the FBI, possess an automated system that is compatible with the III system, be capable of providing electronic criminal history updates and responses to inquiries, and meet certain standards in order to ensure accuracy, completeness, integrity, and security of the information. Currently, all 50 states participate in the III. Agencies can query an individual's descriptive information (name, social security number, date of birth) or identification numbers (state identification or FBI number) in the III to determine if an existing record is in the system. If a record is located, the system automatically retrieves the information from the agency holding the record and forwards it to the requestor.

The National Fingerprint File (NFF) is a separate component of the III. The NFF contains fingerprint and palm print images of all Federal offenders and participating states, districts, and territories. States, districts, and territories can participate in the III alone or in the III and the NFF. Like the III, the NFF is voluntary. Participating states submit the descriptive information, arrest information, state identification number, and the fingerprint and palm print images of an individual's first arrest and the FBI assigns an FBI number. Subsequent arrests are maintained at the local level. As of June 2010, 14 states participate in the NFF (Colorado, Florida, Georgia, Hawaii, Idaho, Kansas, Maryland, Montana, North Carolina, New Jersey, Oklahoma, Oregon, Tennessee, and Wyoming) (<http://www.search.org/about/news/2010/nff.asp>; accessed 21 May 2011).

Current Practice and Future Improvement

The modernization of fingerprint and palm print information and criminal history records has resulted in the combination of both types of information through the use of a live-scan machine. Live-scan technology allows for the digital recording of physical descriptive information, arrest data, capturing of fingerprint and palm print images, mug shots, scars, marks, tattoos, and other information associated with the individual under arrest (i.e., aliases, known associates, addresses, and employment). A key aspect of the live-scan technology is the

ability to conduct immediate searches to verify the identity of an individual while still in custody. Live-scan systems can be integrated into AFIS and criminal history systems, whereby the live-scan feeds information into the agency's other automated systems. A key element to the live-scan technology is the automated quality control function. This ensures that minimum quality standards of the recorded fingerprints and palm prints are met, thus ensuring that quality prints are entering the database. This quality control mechanism also guarantees that the ten rolled fingerprints, the plane impressions, and the palm prints are validated (i.e., the rolled fingerprints of the right hand, the plain impressions of the right hand, and the right palm all correspond).

In the 1990s, the FBI initiated the next stage of fingerprint automation. The new AFIS technology that was developed achieved higher performance standards regarding all aspects of its operations. In July 1999, the FBI implemented this Integrated Automated Fingerprint Identification System (IAFIS). IAFIS combined the new AFIS and the III into one system. A third system, the Identification Tasking and Networking (ITN) was established to manage the workflow information in IAFIS. This workflow involves the computer applications used for processing ten print fingerprint submissions, latent print processing, and record search requests. Through IAFIS, the FBI provides the following services to its customers: criminal and civil ten print submission service, providing electronic images (fingerprints and photographs), latent fingerprint matching, enrollment of unsolved latent prints into a database that is searched by all incoming criminal fingerprint cards, III access, and remote access to IAFIS. Access to IAFIS for latent print processing by external non-FBI authorized users is achieved through the use of free software product provided by the FBI. This software can be installed on desktop personal computers, which are in compliance with the FBI's quality specifications.

Federal agencies in the United States use the Joint Automated Booking System (JABS) as the interface between the live-scan system, the agency's AFIS and IAFIS. With regards to IAFIS, JABS sends the data to IAFIS to determine if the individual has a record in the system, and IAFIS responds back to JABS with the result. Not only does JABS securely and efficiently manage transactions to and from IAFIS but also the system stores the booking data from all the federal agencies. This allows Federal agencies to search for arrests conducted by other Federal agencies.

In 2001, the United Kingdom established an integrated identification service known as IDENT1. IDENT1 integrated friction ridge (fingerprints and palm prints) and criminal history information from Scotland, England, and Wales through the use of desktop workstations and live-scan machines. Features of IDENT1 include known ten print and palm print services, latent fingerprint and palm print searching capabilities, enrollment of latent prints into a database that is searched by all incoming ten print cards, the storage and searching of known prints and latent prints related to specific policing events, and the ability to interface with the United Kingdom's Immigration and Asylum Fingerprint System. Recent improvements include enhanced search accuracy and performance, incorporation of hand-held mobile fingerprint readers, and the development of an open architecture that will allow for the integration of additional biometrics.

The FBI is currently developing their next generation identification (NGI). NGI will address the growing needs of international and national partners. NGI will incrementally replace the existing IAFIS with technical improvements and additional functionalities. Ten print and latent fingerprint services have already been expanded to enable faster and more accurate searching capabilities. Additional capabilities will include the National Palm Print System, whereby agencies can submit known palm prints and can search latent palm prints against the database. An added Repository of Individuals of Special Concern (RISC) will enable agencies to rapidly identify wanted persons, sex offender registry subjects, known or suspected terrorists, and other individuals of special interest. A new 'Rap Back' service will alert participating agencies of criminal activity by employees in positions of trust. The system will also include an Interstate Photo System to facilitate the submission and searching of mug shots, scars, marks, and tattoos. The FBI is moving from a single mode of biometrics (fingerprints) to multimodal. As a result, the NGI will eventually incorporate other biometrics such as iris scans, voice, and facial recognition. This flexible system design will allow for the incorporation of additional biometrics as they emerge.

Conclusion

As technological advances occur, the criminal justice and forensic science communities will continue to take advantage of emerging technologies. Within a 100-year time frame, the science of criminal identification has grown from rudimentary and manual means to automated and highly advanced technologies. With emerging threats to global security, innovation is the key to overcoming the never-ending challenge of an equally innovative criminal element. New technologies will enable international partnerships to be established whereby

biometric and criminal history information can be exchanged on a global scale.

Glossary

AFIS Automated fingerprint identification system.

Biometric system Any system that serves to identify an individual based on anatomical or behavioral traits.

Exemplar A controlled recording of the friction ridge skin used for the purpose of identification; may be taken using black printers ink or Live Scan.

Friction ridge skin The skin on the hands and feet that has both ridges (raised skin) and furrows (depressed skin).

Hit An AFIS designation to indicate that the print that was entered into the system is from the same source as a candidate; some AFIS systems call this an Ident.

Identification A conclusion that may be reached by a latent print examiner after comparing the ridge flow, spatial relationships of minutiae, and, if possible, pore and ridge shapes between a latent print and a known print and

finding sufficient agreement to conclude that the prints were made by the same individual.

Latent print An impression of friction ridge skin that has been recovered from the scene of a crime thorough the use of powder, photography, and/or chemical development.

Live Scan An inkless fingerprinting technology that electronically records friction ridge skin by rolling the skin over a specially coated glass platform and recording the information on a charged coupled device.

Minutiae Locations in the ridge flow on friction ridge skin where a ridge ends or bifurcates.

No Hit An AFIS designation to indicate that the print that was entered into the system is not from the same source as a candidate; some AFIS systems call this a Non-Ident.

Pixel A single unit of a digital image.

Specificity A measure of how often an arrangement of minutiae occurs on the friction ridge skin.

Introduction

Automated fingerprint identification system (AFIS) is a biometric system that is used to identify individuals using fingerprints and palm prints. AFIS was developed in the early 1960s as a means to classify, search, and consolidate ten print records in an automated manner rather than manually. The need for such a system was great, considering that the Federal Bureau of Investigations (FBI) fingerprint database around this time consisted of over 15 million criminal files. In the United States, the FBI collaborated with engineer Joe Wegstein from the National Institute of Standards and Technology (NIST) in order to develop an algorithm capable of matching fingerprints. Fifteen years later, the FBI was using this technology and shortly thereafter, Minneapolis-St. Paul became the first United States city to install an AFIS system. Other nations were creating similar systems as well. Around the same time, France was focusing on creating automated latent print searches. These efforts led to the formation of Sagem Morpho Inc., which recently merged with Motorola's company, Printrak, to establish Morphotrak in the United States. Together, Morpho and MorphoTrak are very prominent worldwide AFIS vendors. In the United Kingdom, research led to the first AFIS vendor that included ridge counts in latent print searches. NEC in Japan visited various AFIS sites before they began developing their AFIS system. They began by working on the issue of matching inked records, and within a year of developing software to do that successfully (1982), they also began conducting latent print searches. In 2003, NEC AFIS software was rated the top performing system in a fingerprint vendor technology evaluation conducted by the NIST that included 18 AFIS vendors.

In the 1980s, there was an experiment conducted in San Francisco, CA, that conducted a test of competing fingerprint

systems latent print matching capabilities. The competitors included Rockwell, NEC, Printrak, and Logica (developed for New Scotland Yard). NEC won the contract for the San Francisco Police Department AFIS system. The system was installed in late 1983 and as a result, there were ten times as many latent print identifications in 1984 and between 1984 and 1986, the city saw a 26% reduction in burglaries. Following this huge success, AFIS systems were rapidly purchased by police agencies; by 1999, the International Association for Identification recognized 500 AFIS sites in the world. The major vendors during this time were Printrak, NEC, Morpho, and Cogent; owing to competition and proprietary rights to the software of each AFIS vendor, interoperability of AFIS systems among different vendors remains a significant problem.

Exemplar Database

AFIS systems contain a digital database of exemplars that is populated with a combination of inked print records that were scanned into the database using a flat-bed scanner and electronic recordings of the friction ridge skin taken using Live Scan technology. It is common for an AFIS database to contain millions of records including both criminal and civil files. Each AFIS record contains a rolled and plain impression of the first finger joint of all 10 fingers and, if obtained, both palms. Demographic data such as the individual's name, date of birth, sex, and any relevant identification numbers are linked to each record.

Before fingerprint and palm print records are added to the database, locations and orientations of bifurcations and ridge endings (collectively called minutiae) are coded, automatically by either the AFIS system or a fingerprint technician. Exemplars typically have minimal background noise, therefore, the

system can accurately determine where a ridge ends or bifurcates, as well as the direction of ridge flow, by measuring changes in the intensity value (zero being black (ridges) and white being a high pixel value (furrows)) of surrounding pixels. On the screen, the locations and orientations of minutiae are shown by a marker with a circle (and sometimes a square for bifurcations, depending on vendor) over the minutiae itself and a tail that points in the direction of the ridge flow. Collectively, the markers make a map of the Cartesian (x, y, θ) coordinates of minutiae (with $(0,0)$ being the lower left corner of the image and θ measuring the angle of rotation from the horizontal). Exemplars of palms generally have hundreds to thousands of minutiae mapped out in this manner, and fingers can have approximately 50–100 features. On the basis of the arrangements of the minutiae, the system defines a pattern type for fingers with the option to cross-refer more than one pattern.

After the minutiae of a new record have been coded, the AFIS system will search the record against all other records in the database to determine if an exemplar for the individual already exists. This can be done in a matter of minutes and it is particularly useful when linking fingerprint records that bear different names/aliases. These types of searches are called *exemplar to exemplar searches* and they are almost 100% accurate in systems where ten print operators check the candidate before consolidating records. When duplicate records do exist, the system may keep only the highest quality record, the most recent record, or several records for an individual depending on site location and the database capacity.

The number of records contained in AFIS databases worldwide is growing everyday as more records are constantly being added. The FBI maintains the largest digital database of ten print records, which contains over 60 million records (both civil and criminal). Besides obtaining their own records, more than 18 000 agencies contribute daily to the database by electronically sending the FBI any felony records they collect. Consequently, the size of the FBI's database increases by up to 10 000 subjects each day, and 96% of those submissions are electronic. INTERPOL, the world's largest police organization, has a database of 104 000 fingerprint records.

Searching Latent Prints in AFIS

The major advantage of having AFIS technology in the field of forensics is the ability to search latent prints recovered from crime scenes against millions of records in a very short period of time. Many times latent prints are recovered at the scene of a crime where there is no suspect. Ideally, a forensic scientist will search recovered latent print evidence through an AFIS system and then be able to provide a person of interest to law enforcement. Not all latent prints can be searched, however. The quality of the latent print must be fairly high, therefore, extreme care must be used when processing latent prints so as to provide the best possible evidence. The latent print must come from a part of the hand that is searchable in AFIS, and the forensic scientist should be confident in the orientation. One must also consider the specificity of the ridge detail and the number of high quality minutiae; six minutiae in a delta (low specificity) are not considered an equal weight of evidence to six minutiae near the core of a tightly wound whorl (high specificity). [Figure 1](#) shows an example of a latent print with a low count of minutiae that would be searched by most latent print examiners, and another latent print with a similar number of minutiae which may be deemed of no value for AFIS entry.

Latent prints that are suitable for entry into the AFIS system are uploaded from a digital capture device or other digital storage media. [Figure 2](#) shows a representative screen shot using a Morpho system where two latent prints have been selected to be searched in AFIS. Each of the latent prints will be coded and searched independently using only the area within the selected boxed regions. The double bar in the box represents 'up' in terms of latent print orientation.

If possible, the forensic scientist will try to limit the search parameters in order to increase the speed of the search and provide the best list of the candidates. This can be done in a variety of ways. The most common way is to designate the pattern type for a finger so that only fingers with those pattern type(s) are searched. The user may choose to limit which fingers or the specific area of the palm to search. If the fingerprint evidence is part of a simultaneous touch with two or

Figure 1 Three latent prints that have a similar number of minutiae but different levels of specificity. The latent print labeled (a) is whorl pattern with high specificity, and high quality; latent print (a) would be searched in automated fingerprint identification system (AFIS) by most latent print examiners. Latent print (b) shows smearing and is of an unknown pattern type. Owing to the quality and low specificity, latent print (b) may not be searched in AFIS by some examiners. Latent print (c) shows a very-high-quality latent print, however it originates from the extreme distal finger tip, a region of the finger where minutiae are not recorded in AFIS, making latent print (c) unsearchable.

more fingers, the user may designate the pattern types of adjacent fingers. If any of these parameters are unknown, the search may be completed with all possibilities of either/both the fingers and/or the palms. AFIS also has the option of marking the cores of the fingerprint and deltas on fingers and palms. There is a tool that allows the user to map the ridge flow if, for example, a palm has a large loop in the hypothenar area. It is recommended that the latent print be entered with the correct orientation; although some AFIS systems have the option of searching a latent print in all orientations, according to NIST Interagency/Internal Report 7775, this can decrease the

efficiency of the system by up to 18%. All of these tools and several others aid the forensic scientist in narrowing the number of records that will be searched, thereby decreasing the time it takes to receive results.

Next, the forensic scientist must code the minutiae in the latent print. Typically, latent prints contain significant 'noise' that can potentially obscure the latent print because of a large variety of reasons (see Figure 1, right and Figure 3, left). This introduces many more shades of gray (or a wider range of pixel values) in latent print images compared to exemplars. This makes it more difficult for the AFIS system to accurately

Figure 2 A screen shot of a Morpho system which shows two latent prints that have been selected for AFIS entry. The double bar at the top of the yellow boxes represents the upward direction. Note the enhancement tools on the right sidebar. Courtesy of Morpho, Inc.

Figure 3 A screen shot of a Morpho, Inc. results screen. The latent print is on the left and the known print is on the right. Circle markers represent ridge endings and square markers represent bifurcations. Courtesy of Morpho, Inc.

autocode minutiae based on the pixel intensity. Most often, the forensic scientist will code the minutiae in latent prints manually to increase the accuracy of minutiae placement. There are several enhancement tools that allow the user to change the contrast, brightness, and magnification of the image to aid in this process.

When all of the coding is complete, the latent print is searched by the system against all of the exemplar records that meet the specifications provided by the user. In most cases, the image is deleted and the only searchable information that remains are the (x, y, θ) positions created by the forensic scientist, although a recent study by NIST indicates that performance increases when both the image and minutiae maps are kept. The arrangement of those coordinates is then compared by the system to every record in the database that fits within the parameters that the user specified to be searched. The thresholds on how different the minutiae can be from any given exemplar vary from vendor to vendor, and because of the proprietary nature of the computer algorithms of these vendors, the exact thresholds are not known. However, each system allows for a given amount of rotation from vertical and x, y positional shifts when searching for a corresponding candidate to account for distortions and the flexibility of the skin.

AFIS Results

The forensic scientist specifies how many of the closest matching candidates they would like returned, and the number chosen varies widely between users, agencies, and crime types. There may also be a default option to have the system designate the number of candidates. When the search is complete, typically in a matter of minutes to just a few hours, the list of candidates will be numerically ranked based on the amount of agreement between the (x, y, θ) coordinates of the minutiae between the latent print and the known record. The images of the latent print and the known record are displayed side-by-side and the forensic scientist can begin comparing them to determine if they are from the same source (see [Figure 3](#)). The forensic scientist may use the enhancement tools on both the latent print and exemplar if necessary. Some systems also have tools that allow the forensic scientist to place markers on both prints in order to more easily note the features they are comparing. The system can also display which minutiae were correlated during the search and also which minutiae were not correlated. Demographic information, such as the candidate's name, ethnic background, or criminal history, is typically not available. If a latent print and a candidate are determined to be from the same source, the forensic scientist will declare a 'Hit' or 'Ident' and will proceed to use the information contained in the AFIS system to locate the original record. If the latent prints are not of the same source, the forensic scientist declares a 'No Hit' or 'Non-Ident' and then continues to compare the next candidate until either a Hit is declared or all of the candidates have been cleared.

If an entire AFIS search is conducted and no candidates result in a Hit, the latent print may be maintained in the unsolved latent print database. The latent prints in this database are searched against every incoming AFIS record on a daily basis, and will continually be searched until the latent print is

taken out of the system by either deletion or a future Hit. Reasons for deleting a latent print may be based on quality factors, crime type, or statute of limitations; the retention policies are determined by the administration of each agency.

The success rate of AFIS returning the proper candidate, provided that candidate exists in the database, is completely dependent on the correlation between the minutiae map of the exemplar and the minutiae map of the latent print. Differences in the coding processes and also the image quality between exemplars and latent prints will inevitably cause slight differences in the exact locations and orientations of the minutiae. Still, care in the coding process is crucial to the success of the system; if there are minutiae incorrectly marked in the latent print, the rank associated with the correct candidate will decrease proportionately, possibly below other (incorrect) candidates. The same is true if the latent print is significantly distorted but accurately mapped, which may cause the relationships of the minutiae to be outside of the system-defined tolerances and then the corresponding candidate would not make the candidate list. Often an unsolved latent print may Hit to an individual that has a new record added to the database but who also had a record in the system at the time of the original search; this demonstrates that the correct candidate may be missed based on minutiae maps being coded by two different sources. Studies by NIST of various vendors showed that success of AFIS is very dependent on the number of minutiae present and the quality of the latent print. It is intuitive that a high-quality latent print with 20 minutiae is more likely to Hit than a low-quality latent print with a low minutiae count. Orientation can also significantly affect the matching capability of the system by up to 18%. If the AFIS system being used differentiates between bifurcations and ridge endings, there is the added possibility that bifurcations were marked as ridge endings and vice versa. AFIS systems with ridge counts may introduce additional error of differing ridge counts in regions where the latent print quality is low. Another factor is having large gaps between coded minutiae – coded clusters of minutiae in latent prints are more effectively searched than latent prints that cover a large surface area but which have minutiae sporadically coded throughout. Creases, especially in the thenar area of the palms, also complicate the agreement between the minutiae coded by the forensic scientist and the autocoded records. Personal communiqué and unpublished studies by Ron Huston (OH, USA) have shown that 50% of palm Hits come from the hypothenar region, the area with the fewest number of creases. The interdigital and lower thenar region each make up about 23–25% of palm Hits, and only about 2% of palm Hits come from the upper thenar area. Note that these statistics may be influenced by the number of latent prints that come from each area of the palm and are not necessarily due to AFIS matching capabilities.

There is growing concern that the use of AFIS systems could result in more erroneous identifications. It is argued that proper testing has not been conducted dealing with the likelihood of an AFIS search producing candidates that have incidental similarities, but are not from the same source. The latent print community uses the term 'close nonmatch' for latent prints that have candidates with similar but not completely corresponding prints. Some researchers believe that latent print examiners must be more cautious when identifying a print as a

result of an AFIS search verses identifying a latent print to a requested comparison subject. This reasoning is based on the premise that the probability of coincidental correspondence between a latent print and an exemplar print is less likely for a single specific individual (often provided as a result of intelligence during a police investigation) versus the same latent print compared to 60 million individuals. The idea is similar to the well-known statistical birthday problem which estimates the probability that a group of any given size will contain two people with the same birthday. Caution should be used when comparing and identifying AFIS candidates, especially for latent prints of low quality, low minutiae count, and low specificity. These factors should be weighed heavily during the analysis phase when a latent print examiner is determining AFIS suitability. Very high quality and specificity is recommended in regions of converging ridge systems (i.e., deltas) which are common in almost all pattern types and in the palm. It is also important that an agency has an effective quality control system that includes verification by a second latent print examiner in order to reduce the chances of an erroneous identification being reported. Current statistical and probabilistic research in the field of latent print identifications are underway and may be used in the future to provide a quantitative way to describe the likelihood that two prints came from the same source, which could be proved to be very useful in the case of low-minutiae-count AFIS cases.

Interoperability

The existence of several AFIS vendors, each of which have developed proprietary algorithms, has led to a problem of interoperability between agencies who may have a reason to search a given latent print through a different database. In 1985, NIST developed standards for how fingerprint records could be shared between various agencies, however these standards were not mandatory to specific vendors. The FBI developed the Universal Latent Workstation (ULW), which is a free software that provides access to the Integrated Automated Fingerprint Identification System (IAFIS) to non-FBI authorized users around the world, as an attempt to make their database available to those who need it. The INTERPOL fingerprint database is accessible to 188 member countries. Unfortunately, private vendors have not made the same efforts and interoperability between neighboring cities, counties, and states remains a serious problem in many areas.

The Future of AFIS

Latent prints and DNA are the only two forensic sciences that have the ability to link a specific individual to a crime scene, and with the speed of the AFIS searches and the low cost of developing latent prints compared to DNA analysis, latent prints remain a crucial part of forensic evidence that is used in the criminal justice system. As such an important identifying tool, there is a significant amount of research being conducted that will improve the system in the future. Research is highly focused on the possibility of including additional features such as pores, creases, and ridge edge shapes, insipient ridges, and dots in AFIS searches. Reproducibility of these features is dependent on the development methods, whether the evidence is

porous or nonporous, and the condition of the donor's skin. In the case of pores, research studies showed that the improvement in matching accuracy was considerably dependent on the quality of both the latent print and the exemplar. The quality and clarity of a latent print must be very high for pore detail to be seen, and the resolution of both the latent print and exemplar should have a minimum of 1000 ppi (pixels per inch) to be useful for this purpose. The implementation of searches that include the above-mentioned details may be conducted after a search using only minutiae did not result in a Hit. Still, the quality must be present in the latent print to include information such as creases and pores, therefore, and the extra time it will take to perform all of the extra coding of the latent print must also be considered. NIST research suggests that the improvement to latent print searches using more than just minutiae is only significant in latent prints with very low numbers of minutiae. Significantly, this means that AFIS systems usually work very well using only the minutiae (second level information) to locate candidates. There are also plans for some vendors to begin including the second and third finger joints in AFIS searches. Like the thenar area of the palm, though, large amounts of creases complicate the ability to accurately code the minutiae in these regions. Currently, the research indicates that level three details improve the matching capability of AFIS only for high-quality latent prints that have a low minutiae count.

The FBI is planning a major upgrade to IAFIS to include more accurate results, upgraded ULW software, and a searchable palm database, called Next Generation Identification and built by Lockheed Martin with the algorithms provided by MorphoTrak. Additionally, it is intended to further increase the interoperability of the FBI's fingerprint database to other federal, state, local, and international AFIS systems. The first increment of this upgrade was implemented in February 2011, and replaced AFIS with Advanced Fingerprint Identification Technology to provide significantly improved matching algorithms. The full system upgrade is planned for 2014.

With the speed, accuracy, and many aspects of functionality, the AFIS has become a critical component to the law enforcement system. The amount of information searched in a few hours using an AFIS system could not be completed in a human lifetime. AFIS is arguably the most significant addition to the forensic science discipline in the last 25 years with respect to the cost, speed, and number of investigative leads that have come from these algorithm-based searches. It is an ever evolving system that will continue to be researched and improved upon for years to come.

GC-MS Gas chromatography-mass spectrometry

MALDI-MSI Matrix-assisted laser desorption/ionization mass spectrometry imaging

SIMS Secondary ion mass spectrometry

Introduction

The impressions left by friction ridge skin on the grasping surfaces of the hands (and feet) not only demonstrate contact, but are also sufficiently discriminating to allow personal identification. They are thus extremely important in criminal investigations to establish links between the objects, victims, and suspects. The most common forms of these impressions are latent (hidden) fingerprints, and successful recovery from a scene or object relies on their detection. A range of physical and chemical methods have been developed over the years for the visualization of latent fingerprints. These methods target differences between the latent fingerprint and the substrate on which it is laid and are based either on physical attraction or a chemical reaction. Knowledge of the chemistry of latent fingerprints is critically important in understanding detection methods.

Latent fingerprints are considered to be an emulsion of aqueous and lipid components derived from natural skin secretions, contaminants, and other skin debris such as dead skin cells. At deposition, they typically comprise a thin film of residue approximately 0.1 μm thick and less than 10 μg in weight. The chemistry of the latent fingerprint on deposition may be affected by a number of donor factors such as age, gender, diet, disease state, medication, and the presence of exogenous contaminants on the surface of the skin. Over time, the chemical nature of the deposit will change through evaporation of components, microbial action, and exposure to the air. The rate of change will be dependent on the chemistry of the original deposit and the surrounding environment. Donor variability and aging of the deposit will have a significant effect on the successful detection of latent fingerprints. However, most fingerprint detection procedures have been developed from the knowledge of human skin secretions without regard to these factors.

Since most chemical reagents used in fingerprint recovery procedures are developed on this theoretical model of latent fingerprint residue, there is an incentive to pursue a more accurate understanding of fingerprint composition if researchers are to develop new and more effective reagents. The degradation of fingerprints presents a significant setback for criminal investigations, as many visualization techniques are ineffective on latent fingerprints more than a few months old. In addition to the discovery of new reagents, there is still a need for further research to gain a better understanding of the reaction mechanisms associated with established reagents and those still under development.

Over the past few years, there have been several studies on fingerprint composition, namely, to establish if any compositional variations can be attributed to traits such as age or gender and to characterize the changes in fingerprint composition that occur with degradation under various conditions. This would enable the optimization of latent fingerprint development techniques currently used by forensic laboratories, as well as the development of new, more effective methods, thus providing improved fingerprint detection.

The most commonly used analytical technique is gas chromatography-mass spectrometry (GC-MS). Other techniques employed in recent years include Fourier transform infrared spectroscopy, Raman spectroscopy, desorption electrospray ionization MS imaging (DESI-MSI), matrix-assisted laser desorption/ionization MS imaging (MALDI-MSI), and secondary ion MS (SIMS). These methods are advantageous over GC-MS, as they require little or no sample preparation and are nondestructive of fingerprints, allowing changes over time to be monitored.

A major problem in analyzing the chemical composition of a latent fingerprint is overcoming the problem of sampling. Some studies analyze fingerprints prepared by having the donor rub a fingertip on the skin to collect sebum, whereas

others clean the fingertip with a solvent and allow perspiration to accumulate before fingerprint deposition. Earlier studies have not used latent fingerprints at all but have collected material directly from the fingertip via solvent extraction. This creates some problems in making comparisons between studies, considering the solubilities of the various compounds in certain solvents, as these results will unsurprisingly only report compounds amenable to the solvent extraction procedure used. Due to the complex nature of fingerprints, most studies thus far have investigated only certain groups of components rather than the entire known range of compounds. Amino acids, fatty acids, and sebaceous lipids have been studied most often, as these compounds are of greatest forensic relevance.

To date, the results of the analysis of recently deposited fingerprints are consistent with those expected from the analysis of sweat and sebum. It has also been established that there are significant differences in the lipid content of latent fingerprints deposited by prepubescent children and adults, with children's fingerprints containing a greater proportion of volatile compounds. While many current fingerprint development methods are unable to detect the nonvolatile portion of children's fingerprints, potential target compounds in children's fingerprints for future detection techniques have recently been identified. Studies regarding the effects of time and environment on deposited fingerprints indicate a general trend of loss of material, especially within the first 3 months, attributed to bacterial action, oxidation, and evaporation of volatiles. Further studies are required to determine the effects that factors such as an individual's age, gender, ethnic background, or health may have on latent fingerprint composition.

This article provides an overview of the chemical composition of latent fingerprints and a discussion of recent approaches to investigate the factors affecting fingerprint composition. This overview by necessity is limited in length, and for a comprehensive review of the chemical composition of latent fingerprint residues, readers are directed to the chapter by Robert Ramotowski listed in the Further Reading.

Sources of Fingerprint Residue

The endogenous substances found in latent fingerprints are derived from the secretions of the eccrine (sweat), sebaceous, and apocrine glands located within the dermis, as well as the constant sloughing of dead cells by the epidermis (Table 1). Current models of latent fingerprint composition are based on medical research on the secretions of the skin glands, although this does not provide an exhaustive list of the hundreds of compounds that may be present. For the purpose of latent fingerprint detection, the most important sources of material are the secretions of the eccrine and sebaceous glands, as secretions from the apocrine glands are rarely a significant component of latent fingerprint residue due to their location in the body.

Eccrine glands serve to dissipate body heat through the evaporation of sweat from the skin surface and to excrete excess water, electrolytes, and waste products such as urea. These glands, located within the dermis, are coiled, tubular structures, which lead directly to the skin surface. As the eccrine glands are the sole type of secretory gland on the palms of the hands, located along the skin ridges, latent fingerprints always contain at least some eccrine sweat components. Eccrine sweat is an aqueous mixture consisting primarily of salts, amino acids, and some lipids. The response of the eccrine glands to elevated temperatures is gradual and weak but is much stronger and more immediate when stimulated by stress; the latter is thought to be an important factor in the deposition of latent fingerprints at crime scenes.

Sebaceous glands are found all over the body, except for the palms of the hands and soles of the feet. The sebaceous glands consist of one or several lobes, encapsulated by highly vascularized connective tissue. The oily mixture produced by these glands, known as sebum, is usually secreted into hair shaft canals and is present in greatest density on the forehead and scalp. The main functions of sebum are thought to include lubricating the skin and hair, waterproofing the epidermis, transporting antioxidants, and providing individuals with a unique scent signature. The production of sebum is largely under the control of androgens, in particular, testosterone. These hormones cause an increase in sebaceous gland size,

Table 1 Human skin secretory glands

<i>Types of glands</i>	<i>Secretion types</i>	<i>Body distribution</i>	<i>Role of gland</i>
Sebaceous	Sebum (lipids)	Typically localized to regions containing hair follicles	Inhibits the growth of bacteria, lubricates and protects the keratin of the hair shaft, and conditions the surrounding skin
Sweat (sudiferous) glands Eccrine (merocrine)	Sweat (aqueous)	Entire body, highly concentrated on the palms of the hands and soles of the feet	Cooling the surface of the skin to reduce body temperature, excretion of water, electrolytes and metabolites, and protection from environmental hazards
Apocrine	Sweat (aqueous)	Associated with hair follicles around the axillary regions. In particular, the armpits, groin, and chest	Scent glands (pheromones)

which has a direct effect on the production rate of sebum. Changes in androgen levels that occur with age therefore impact sebum production over the course of an individual's lifetime. Sebum is incorporated into latent fingerprints through the individual touching his/her face or hair, and it provides the majority of the lipid content in fingerprint deposits.

As eccrine glands are the only glands present on the grasping surfaces of hands, they contribute greatly to the aqueous component of latent fingerprints. However, due to activities such as touching the face or hair, hands will often be contaminated with sebaceous secretions. Thus, while one type of secretion may predominate in a latent fingerprint, there can be no purely eccrine or purely sebaceous fingerprint (Table 2).

The most abundant compounds in eccrine sweat include salts and amino acids. Sodium chloride is the most abundant compound present in eccrine secretions and makes up the

majority of the inorganic salt content, together with potassium chloride. Lactate salts are the second most abundant component of eccrine sweat and are thought to be one of the target molecules for cyanoacrylate fuming. The presence of lactate is indicative of eccrine gland activity, as it is derived from glucose utilization; however, lactate concentration decreases as sweat rate increases over time. Eccrine sweat also contains trace amounts of various metals such as zinc, copper, and manganese, as well as drugs and hormones and their metabolites, which diffuse into the eccrine glands from blood plasma.

The presence of amino acids in human sweat has been widely reported in the biomedical literature, with a wide range of amino acids identified (Table 3). Up to 22 amino acids may be present in eccrine sweat, including those involved in the urea cycle. The most abundant amino acids include serine, glycine, ornithine, alanine, and aspartic acid, although

the types and concentrations of amino acids present will depend on a variety of factors including general health, diet, gender, and age. It has also been reported that the abundance of amino acids may be up to 18 times higher in sweat produced during exercise than from thermal stimulation.

Amino acids are of particular interest when considering the detection of latent fingerprints on paper. When transferred to such a substrate, the amino acids bind strongly without significant migration, provided the paper does not get wet or exposed to high levels of humidity (see [Figure 1](#)). Latent fingerprints formed this way can be developed decades after deposition.

Sebum consists of a mixture of lipid compounds including triglycerides, fatty acids, wax esters, cholesterol, and squalene ([Table 4](#)). As with eccrine sweat, the composition of sebum can be affected by various factors such as age, health, genetics, and diet. The lipids secreted by the sebaceous glands are unusual compared to other lipids found in the human body, in that they consist of a higher proportion of unsaturated and branched-chain molecular structures, allowing sebum to remain as a liquid film on the skin surface due to its low melting point of 30 °C. Some components of sebum, such as wax esters and some fatty acids, are produced exclusively by the sebaceous glands, and so their concentration is correlated directly to gland activity. Squalene is produced in all tissues, but it is usually rapidly metabolized to cholesterol. It is only in the skin that squalene reaches significant levels, but the reason for this is unknown. Sebum cholesterol itself is thought to be actually of epidermal origin. Free fatty acids are not produced in the sebaceous glands but on the skin surface, as epidermal and bacterial lipases hydrolyze triglycerides to fatty acids, diglycerides, monoglycerides, and glycerol. The durable nature of the nonvolatile sebaceous materials such as triglycerides and wax esters provides a means to detect latent fingerprints that have been exposed to water, for example, with physical developer.

Factors Affecting Fingerprint Composition

Substrate

For the purpose of latent fingerprint development, surfaces are broadly categorized into porous and nonporous, based on their ability to absorb fingerprint residue. Paper and cardboard typify the former; glass and metals, the latter. There is also a third, intermediate category of semiporous surfaces, which

encompass any substrate with a combination of porous and nonporous surface properties, such as painted surfaces and some polymers. The surface type will largely determine the development techniques to be used, based on the interactions between certain fingerprint compounds and the surface, as well as the compatibility between the reagent and the surface.

Substrates with greater porosity will absorb fingerprint residue to some degree during deposition, with the end result that fingerprints on porous substrates typically contain more material than those on nonporous surfaces. For instance, it has been shown that up to three times more amino acid material is found in fingerprints on porous surfaces than those on nonporous surfaces. Eccrine sweat is more readily absorbed than sebum; therefore, the former is more efficiently transferred onto porous surfaces, while the latter will remain on the surface of the substrate for up to several years following deposition.

Deposition

The physical contact of the fingertip with a surface is clearly important in determining the initial composition of fingerprint residue. Not all substances on a fingertip are transferred on contact, which is easily demonstrated by the production of a depletion series of fingerprints. Parameters involved in the deposition process include duration of contact, contact angle, electrostatic forces, surface temperature, and pressure. For example, applying excessive pressure during deposition leads to a greater amount of residue being deposited but will cause the ridges of the fingertip to distort, reducing the clarity of the resulting fingerprint.

It is difficult to determine the precise influence of these parameters in isolation from the nature of the surface itself. Studies have indicated that both the quantity and type of material transferred are dependent on substrate type. Currently, it is not clear whether this transfer process is due to physical or chemical interactions and represents an important unexplored area of scientific study.

Donor

The chemical composition of material found on the fingertips of individuals is known to differ between people but it also varies over time with a single individual. There are numerous factors that affect perspiration rates and material secreted. It has been suggested that should a fingerprint be of insufficient clarity to provide identification, the composition of the fingerprint residue could provide important clues about an individual, such as age, gender, or personal habits.

There is a significant difference in fingerprint composition between prepubescent children and adults due to the marked increase in sebaceous gland activity that occurs at the onset of puberty. Anecdotal evidence has suggested that fingerprints deposited by young children evaporate within a relatively short time frame, whereas adults' fingerprints are rather more durable under the same conditions. This presents a great difficulty to the investigation of crimes involving children, such as abduction, as the victim's fingerprints will evaporate within a few days following deposition. It has since been established that children's fingerprints contain a greater proportion of volatile lipids, which accounts for their short-lived nature.

As sebum production is under the influence of androgen levels, males tend to produce more sebum than females across all age groups. However, attempts to distinguish between genders based on fingerprint composition have thus far failed to find any significant differences. Other factors known to affect the composition of eccrine and sebaceous secretions include health, diet, and medication, with xenobiotics and their metabolites excreted by the eccrine glands.

To date, no other significant compositional differences have been linked to donor traits apart from pre- and post-pubescence. Rather, many studies have commented on the significant variation found between individuals, indicative of the combined influences of several factors contributing to fingerprint composition.

Contaminants

Incidental contact with a wide range of materials through everyday activity can introduce a significant amount of exogenous contamination onto the fingertips, which are then incorporated into latent fingerprints. Such contaminants include commonplace substances such as food residues and cosmetic products; however, compounds of forensic relevance may also be present in fingerprints in detectable levels. To this effect, various studies have been conducted that have successfully identified contaminants from recently handled items, such as legal and illicit drugs (including metabolites, which indicate use rather than just handling), explosive residues, and fibers, from latent fingerprints.

Ambient Conditions and Time

Apart from the factors that affect the initial composition of fingerprint residue, there are a number of potential parameters that affect the chemical composition of latent fingerprints after deposition. Fingerprint residue begins to degrade almost immediately after deposition by processes including evaporation of volatile components, oxidation, environmental factors, and bacterial activity. The rate of degradation is dependent on the initial chemical composition of the residue, as well as the environmental conditions. Exposure to UV light, temperature, and humidity has some effect on degradation and thus on the ability of forensic personnel to recover latent fingerprints. In recent years, there has been increased interest on the factors affecting the degradation of fingerprint residue over time.

One of the first stages of fingerprint degradation is the evaporation of water and volatile lipid constituents, leaving an increasingly viscous, waxy residue. Up to 85% of a latent fingerprint may evaporate within 2 weeks following deposition; however, children's fingerprints evaporate much faster due to their higher proportion of eccrine and volatile compounds. The salts present in eccrine sweat are nonvolatile and crystallize on the surface becoming subject to degradation by both exposure to UV light and erosion by airflow. On porous surfaces, substances such as chloride and urea begin to diffuse through porous surfaces approximately 1 week following deposition, and the rate of diffusion will be hastened by humidity.

It has been observed that fingerprint lipids undergo a gradual breakdown to their constituent fatty acids and that fingerprints stored in the dark degrade less rapidly than those stored under direct light. Over a period of 60 days, there is an initial increase in the level of shorter-chain fatty acids, followed by a subsequent decrease. This is possibly due to oxidation or bacterial degradation of long-chain fatty acids, wax esters, and triglycerides, generating short-chain fatty acids, which later evaporate or are degraded further. Squalene, being a highly unsaturated compound, is readily oxidized to hydroperoxides and squalene epoxide, which themselves degrade to volatile compounds such as aldehydes and ketones, in a process accelerated by exposure to UV light and deposition on a nonporous substrate. Children's fingerprints degrade differently than those left by adults because of the lower lipid content in their fingerprints.

Other factors that can affect the detectability of a fingerprint include immersion and fire damage. As many amino acids and inorganic salts are water soluble, exposure to rain or high humidity has detrimental effects on these constituents. Lipid-specific reagents have proven effective on substrates submerged under laboratory conditions, although documents recovered from water sources may be less successful due to the presence of contaminants or degradation by microbial action.

Several studies have investigated the effect of pyrolysis (as may be encountered in cases involving arson or firearms) on fingerprint constituents, indicating that excessive temperature can cause new pyrolytic products to form, which could be used as targets for development reagents. Exposure to temperatures in excess of 100 °C is a known cause of thermal degradation of some amino acids and urea fingerprints. Lactate is also subject to both thermal and photodegradation.

It has been suggested that knowledge of fingerprint degradation could be used to date fingerprints, thereby placing an individual at, or excluding them from, the scene of a crime at the time it occurred. More research is needed in this area to fully understand the factors affecting degradation, with evidence to suggest that substrate type may influence some processes.

Future Directions and Conclusions

Given the value of fingermark evidence in law enforcement, improvements in their detection will have a significant effect on successful investigation of terrorism and crime. However, the ability to make future improvements to current fingermark detection methods and the development of new approaches to the visualization of latent fingermarks depend critically on a greater understanding of the chemistry of the fingermark residue.

A major challenge is the development of a 'standard' latent fingermark, vital for establishing the effectiveness of new detection methods and for quality assurance and quality control in fingermark detection. The lack of suitable analytical standards for research on the development and optimization of novel and existing formulations is a significant ongoing issue. Quality control tests of reagents and comparisons between different formulations and application methods are often performed using latent fingerprints collected from a small, local sample population. Due to variation in fingerprint

composition, reproducibility thus becomes difficult, especially when comparing results across several studies. The absence of standard methodologies introduces additional variation, as some tests may collect 'charged' fingerprint samples containing sebum, whereas others use 'natural' fingerprints, further complicating objective comparisons.

Attempts have been made to address this problem by spotting solutions of the relevant target compounds in serial dilutions onto strips of paper or using a modified inkjet printer. In this way, 'fingerprints' of consistent, uniform quality may be printed on paper for subsequent treatment with reagents such as ninhydrin and physical developer. However, as these test strips only contain the target compounds of specific development reagents, they are applicable to only a few techniques at best and cannot replicate any interactions between compounds, which may also affect development. A more realistic approach would be to use a standard more closely modeled on actual fingerprint composition.

The studies currently underway around the world on the fundamental chemistry of latent fingermarks will provide a platform for the development of the next generation of latent fingermark detection methods. They will also provide a step toward the development of a 'standard' latent fingermark that may be used as an analytical standard, thereby ensuring experimental reproducibility and enabling comparisons between different laboratories by removing variables derived from natural fingerprint variation.

Glossary

Algorithm A step-by-step procedure for solving a problem or accomplishing some end, especially by a computer.

Anthropometry Distinct measurements of the human body.

Arch A pattern type in which the friction ridges enter on one side of the impression and flow, or tend to flow, out the other side with a rise or wave in the center. Arches are subdivided into plain and tented arches.

Automated fingerprint identification system (AFIS) A generic term for a fingerprint matching, storage, and retrieval system.

Bifurcation The point at which one friction ridge divides into two friction ridges.

Classification system Alpha numeric formula of finger and palm print patterns used as a guide for filing and searching.

Dermal papillae Peg-like formations on the surface of the dermis.

Dermis The layer of skin beneath the epidermis.

Differentiation Becoming different, that is, the cells of an embryo differentiate into organs and parts as it grows; specific friction ridge patterns become unique.

Embryology A branch of biology that deals with the formation and development of embryos.

Enclosure A single friction ridge that bifurcates and rejoins after a short course and continues as a single friction ridge.

Ending ridge A single friction ridge that terminates within the friction ridge structure.

Epidermis The outer layer of the skin.

Friction ridge A raised portion of the epidermis on the palmar or plantar skin, consisting of one or more connected ridge units.

Friction ridge skin Corrugated skin on the volar areas that enhances friction of the surface.

Furrows Valleys or depressions between friction ridges.

Henry classification An alpha-numeric system of fingerprint classification named after Sir Edward Richard Henry used for filing, searching, and retrieving ten-print records.

Identification The determination by an examiner that there is neither sufficient agreement to individualize nor sufficient disagreement to exclude.

Impression Friction ridge detail deposited on a surface.

Incipient ridge An incipient ridge is an immature friction ridge.

Known fingerprints The fingerprints of an individual, associated with a known or claimed identity, and deliberately recorded electronically, by ink or another medium. Also known as exemplars.

Latent print Transferred impression of friction ridge detail not readily visible. Generic term used for unintentionally deposited friction ridge detail.

Loop A type of pattern in which one or more friction ridges enter upon either side, recurve, touch or pass an imaginary line between delta and core and flow out, or tend to flow out, on the same side the friction ridges entered. Loops are subdivided into radial and ulnar loops.

Minutiae Events along a ridge path, including bifurcations, ending ridges, and dots (also known as Galton details).

Mugshot Police photograph of a suspect's face or profile.

Papillary ridges Orderly rows of eccrine glands positioned along the path of the friction ridge.

Pattern type Fundamental pattern of the ridge flow: arch, loop, whorl.

Persistence Having lasting qualities; remaining the same; nonchanging.

Primary ridge Ridge on the bottom of the epidermis under the surface friction ridges.

Recidivist A habitual criminal.

Secondary ridges Ridges on the bottom of the epidermis under the surface furrows.

Short ridge A single friction ridge beginning, traveling a short distance, and then ending.

Spur A bifurcation with one short friction ridge branching off a longer friction ridge.

Volar pad Palmar and plantar fetal tissue growth that affects friction ridge skin development and patterns.

Whorl A fingerprint pattern type that consists of one or more friction ridges that make, or tend to make, a complete circuit, with two deltas, between which, when an imaginary line is drawn, at least one recurving friction ridge within the inner pattern area is cut or touched. Whorls are subdivided into plain whorls, double loops, pocket loops, and accidental whorls.

Introduction

The classification and identification of friction ridge impressions rests on the two principal foundations of friction ridge skin: uniqueness and persistence. These two premises are

rooted in the scientific research conducted on the development and structure of friction ridge skin coupled with empirical studies. It was this marriage of research and application that led to the establishment of friction ridge impressions as the primary method of personal and criminal identification.

Development of Friction Ridge Skin

The embryology of fetal growth is well researched and documented in the scientific literature. At 5 days post-fertilization, embryonic cells are differentiating into nerve cells, blood cells, skin cells, and so on. At approximately 6 weeks gestational age, the hands have developed into flat-like scalloped paddles representing the 5 digits. At the same time, the volar pads begin to appear. Volar pads are areas of swollen undifferentiated connective tissue, known as mesenchymal tissue. The placements of the volar pads are predetermined in all normal and healthy human fetuses. Any deviations are due to genetic deformation or disease. While the initial placement of the volar pad is predetermined, the specific location, shape, and size of the volar pad influences the friction ridge pattern.

The volar pads stop growing at about 10 weeks, and by 12 weeks the pads are being reabsorbed back into the hand. As the volar pads shrink, the friction ridges of the fetus start to develop on the bottom of the epidermis, projecting down into the dermis. These ridges, known as primary ridges, continue to proliferate and within 3–4 weeks, the entire underside of the epidermis contains primary ridges that are anchored in the dermis. The proliferation of the primary ridges and the resulting paths and path deviations are random and dependent upon localized stresses and growth factors due to genetics and environment factors. It is this randomness both in the growth of the fingers and the proliferation of the ridges that contributes to the formation of a unique arrangement of friction ridge skin.

Each ridge consists of ridge units that have formed together, with each unit containing a sweat gland (14th week). The number of ridge units that then form into a ridge is random and dependent on genetic and physical variances that constitute growth. By the 15th to 17th week, primary ridge proliferation ceases. At this point, secondary ridges start growing between the

rows of primary ridges and down into the dermis. Although the proliferation of primary ridges has ceased, growth continues and the ridges push up through the surface. Beginning at approximately 17 weeks, the epidermal ridges can be viewed on the epidermis. Unlike primary ridges, secondary ridges do not contain sweat glands. Secondary ridge proliferation continues until 24 weeks. At this point, there is a one-to-one correspondence between the primary and the secondary ridge. The path of the primary ridge corresponds to the epidermal surface friction ridge, whereas the path of the secondary ridge corresponds to surface furrows that exist between friction ridges (Figure 1). By the fifth month of fetal development, all friction ridge growth and proliferation has taken place and is established in its permanent form. This permanent formation can be viewed as the template that is maintained throughout one's life. Once friction ridges and their paths are established, the only factor that may cause a change in the template is damage down into the dermis.

Structure of Friction Ridge Skin

There are two types of skin: thin and thick skin. Thin skin covers most of the body and contains hair follicles, pigment, smooth muscles, and sebaceous glands (glands that secrete a waxy matter called sebum that lubricates the skin and the hair). Friction ridge skin is considered thick skin and is hairless, has no pigment, and contains sweat glands. Friction ridge skin covers the palmar area of the hands and the plantar area of the feet. It is considered specialized skin that serves to aid in grasping and holding. Like all skin, friction ridge skin is composed of two layers: epidermis, the outermost layer, and dermis, the underlying vascular support for the epidermis.

Thick skin epidermis contains five layers (Figure 1), starting from the bottommost layer to the topmost: (1) stratum basale,

Figure 1

(2) stratum spinosum, (3) stratum granulosum, (4) stratum lucidum, and (5) stratum corneum. The stratum basale is also known as the generating layer because this is the layer that generates new skin cells through mitosis that then migrate up through the remaining layers. Cells in this layer are columnar in shape and flatten out as they progress to the surface where they eventually die. Cells that move into the stratum spinosum layer start to synthesize keratin, the structural protein that makes up skin, and begin to take the shape of a polygon. In the stratum granulosum, cells are increasingly flattened and filled with keratin proteins and waterproofing lipids. This is the last layer of skin that is considered alive. The next layer of skin, the stratum lucidum, is only present in thick skin and is considered as a barrier layer of skin because of its waterproofing properties. The outermost layer, the stratum corneum, contains flat cells composed mainly of keratin protein in order to absorb water, provide strength, and serve as a protective layer. The progression of a cell from the stratum spinosum layer to the stratum corneum takes approximately 60 days. The structural integrity of the migrating skin cells is maintained by desmosomes, cell-adhesion proteins that tightly link adjacent cells together.

Connecting the epidermis to the dermis is the basement membrane. This connective tissue is strongly attached to the epidermis through fine fibers known as hemidesmosomes. The dermis is divided into two areas: (1) the papillary region and (2) the reticular region. The papillary region contains dermal papillae (Figure 1). Dermal papillae are fingerlike projections arranged into double rows, increasing the surface area between the epidermis and dermis, thereby strengthening the juncture with the epidermis and increasing the amount exchange of oxygen, nutrients, and waste. With regard to thick skin, the dermal papillae are extremely prominent. As a result, the epidermis follows the contour of the prominent double rows of dermal papillae. Each double row of dermal papillae corresponds to a surface friction ridge. The reticular region is composed of thick connective tissue that supports larger blood vessels and nerves.

Historical Scientific Research into Friction Ridge Skin

The use of fingerprints as a means of identification has existed for thousands of years. While early applications of fingerprint impressions specifically associated an impression left by a person with that person's identity, scientific research into the study of friction ridges did not start until the mid-to-late 1600s. This early research documented the anatomical and morphological structure of friction ridge skin.

In 1684, Nehemiah Grew studied the anatomy of the friction ridge skin and described the ridges, their arrangements, furrows, and sweat pores. His work contained accurate drawings of the palms, to include fingerprint patterns. A year later, Govard Bidloo (1649–1713) illustrated papillary ridges on the underside of the fingers. His book also contained a drawing of the friction ridges on a thumb. Marcello Malpighi (1628–94) was the first to use the microscope to detail the different layers of skin and the form, structure, and function of friction ridge skin in his 1686 treatise *Concerning the External Tactile Organs*.

Continuing scientific research led anatomist J.C.A. Mayer to conclude in his book *Anatomical Copper-Plates with Appropriate Explanations* (1788) that while friction ridge patterns may bear a certain likeness, the formation of the individual ridges is random

and they are thus never duplicated. This was the first observation that friction ridge patterns can be classified while the specific arrangement of the ridges and deviations therein are unique.

The first detailing of the different types of fingerprint patterns was by Johannes Evangelista Purkinje in his 1823 thesis *Commentary on the Physiological Examination of the Organs of Vision and the Cutaneous System*. Purkinje classified and illustrated nine different patterns, which served as the historical basis for future systems of fingerprint classification.

In 1883, Dr. Arthur Kollmann researched the fetal development of friction ridges in his book *The Tactile Apparatus of the Hand of the Human Races and Apes in Its Development and Structure*. Kollmann was the first scientist to determine that friction ridges are formed by the sixth month. Kollman identified embryological volar pads, the swelling of loose connective tissue, present on the hands and feet. He also formulated the theory that differential growth, caused by random stresses on the forming friction ridge skin, influenced friction ridge development.

One of the most prolific researches into friction ridge skin was by Harris Hawthorne Wilder. Over a 30-year period, Wilder researched the evolution, genetics, formation, structure, and differential growth of friction ridge skin. In conjunction with Bert Wentworth, a Police Commissioner in Dover, New Hampshire, Wilder authored the influential book *Personal Identification* in 1918. In this book, Wilder and Wentworth formulated the premise that, due to differential growth, all friction ridge skin is unique.

Modern scientific research into the embryological growth and development of friction ridges continued to support the premise that friction ridges are unique due to differential growth. Dr. Harold Cummins known as the "Father of Dermatoglyphics" conducted the most extensive research into the study of friction ridges. He researched volar pad formation, development during key stages of fetal growth, to include growth during times of disease and genetic abnormality, and uniqueness of friction ridge skin. With Charles Midlo, Cummins authored the book *Fingerprints, Palms, and Soles – An Introduction to Dermatoglyphics* in 1943.

Like Cummins, Dr. Alfred Hale conducted extensive research into the development and differential growth of friction ridges. Hale analyzed thin cross-sections of fetal skin to document friction ridge growth and development at various stages. This significant research was published in his paper "Morphogenesis of the Volar Skin in the Human Fetus." Building on the foundations established by Cummins and Hale, Michio Okajima, researched immature friction ridges, known as incipient ridges, and established their uniqueness and permanence.

Research by Dr. William Babler into the prenatal development of friction ridge skin has solidified the theory that volar pad shape and the timing of primary ridge formation determine pattern type and the width of the volar pad is a factor in ridge configuration. In addition, Babler also established that the bone width of the distal phalanx, the last digit in each finger or toe, influences the friction ridge pattern.

Uniqueness and Permanence – The Foundations of Friction Ridge Identification

The previous sections discussed the development and structure of friction ridge skin. The scientific research into both areas has

established that friction ridge skin is both persistent and unique. The fact that epidermal cells are cemented together by desmosomes, coupled with the fact that the stratum spinosum is firmly attached to the dermis via the basement membrane, is the structural basis for the permanence of friction ridge detail. This structuring of the epidermis and the dermis allows for the renewal of skin cells while maintaining the friction ridge arrangements. As previously mentioned, the friction ridge template established in the developing fetus does not change throughout one's life except for the occurrence of damage to the dermis. However, while the damage may alter the friction ridges in a specific location, the resulting scar is both permanent and unique.

The principle of uniqueness of friction ridge configurations has been strongly supported by the research conducted in the fetal development of friction ridges. This research has demonstrated that primary ridge proliferation and the resulting ridge paths are mostly random and dependent upon random, localized stresses. Ridge units that make up each ridge populate randomly yet are influenced by the randomness of the units within the same vicinity. As a result, developing ridges are influenced by the random paths of other ridges that surround them. This random proliferation creates ridges that continue, stop, split, or develop spurs or islands. This random proliferation is also believed to be influenced by the environment of the growing fetus. While a fetus may be predisposed to a certain pattern type (arch, loop, or whorl) due to genetics (genotype), the specific path and its deviations are individual (phenotype) and not genetically controlled (although they may be highly influenced by pattern type or disease conditions). The prevailing theory of random ridge development is that the environmental experience of every fetus will never be duplicated. The exact pressures that a fetus experiences will always be unique to each fetus, including that of a twin growing in the same womb.

Early Applications of Friction Ridge Identification

In the mid-to-late 1800s numerous scientific studies proposed that friction ridges are both unique and persistent. However, these two premises of friction ridge identification had not been applied outside the scientific arena. It was not until Sir William Herschel, Dr. Henry Faulds, and Sir Francis Galton articulated these premises that the groundwork was laid establishing that fingerprints could be used to identify recidivists, used in forensic science applications, and accepted as evidence in courts of law.

As a magistrate in India, Sir William James Herschel realized the utility of using friction ridge impressions for identification purposes on a large scale. He instituted the use of leaving one's fingerprints or palm prints as a signature for pension payments, authenticating transactions, and the fingerprinting of criminals to ensure that jail sentences were not carried out by a paid imposter. Herschel also researched fingerprint impressions obtained from friends and family members that he collected over the years, and observed that friction ridges were both unique and persistent. While Herschel was instrumental in the institutionalization of fingerprints as a means of personal identification, his work did not extend to the realm of catching criminals.

In Japan, Dr. Henry Faulds, a Scottish missionary, began research into the use of friction ridge impressions as a method of identification. After developing a method of recording inked impressions of each finger on a card, Faulds began to amass a large collection of fingerprint cards. Faulds analyzed this collection and determined that each impression in his sampling was unique. In addition to researching the individualizing power of friction ridges, Faulds explored the persistence of friction ridges by observing friction ridges growing back exactly the same after minor destruction. Faulds also observed persistence with relation to human growth by analyzing the friction ridges of children over a 2-year time period. The concept of uniqueness was first utilized in a criminal investigation when a member of Dr. Henry Faulds' staff was accused of burglary. Faulds compared the latent print left by the perpetrator with the known prints of the accused staff member and concluded that the prints were not the same. This is considered the first latent print comparison used in relation to a criminal matter. In 1880, *Nature* magazine published an article written by Faulds in which he described the comparison of latent prints to known prints as evidence in criminal proceedings. Although Faulds specifically referenced the use of fingerprints left at crime scenes, the use of latent prints in criminal proceedings did not occur for a number of years and was not associated with the work of Faulds.

In 1888, Francis Galton, the cousin of Charles Darwin, began investigating fingerprints in preparation for a lecture on personal identification. In his investigations, Galton reviewed the work of Herschel and Faulds. Realizing the value of friction ridge impressions, Galton began his own scientific research. Galton collected over 8000 fingerprint impressions in order to study the fingerprint as a whole and the minutiae contained within each fingerprint. Four years of empirical studies resulted in Galton publishing his seminal work on friction ridges in 1892. In his book, *Finger Prints*, Galton detailed why and how fingerprints are unique and persistent. He also was the first to define and name the friction ridge deviations, known as minutiae, in a fingerprint. He described a bifurcation, ending ridge, short ridge, and enclosure. Galton's detailing of the uniqueness and persistence of friction ridges and its minutiae provided the foundation for the use of friction ridge identification in criminal proceedings (administrative and forensic).

After proposing the principles of uniqueness and persistence of friction ridges, the ability to associate a latent print left at a crime scene with a record print became a reality. In the years following the publication of Galton's book, police agencies determined that accidental recordings of fingerprints left at crime scenes could be compared to the prints of known individuals in order to solve criminal cases. As a result, the use of latent print impressions as evidence in criminal proceedings has been institutionalized in both the criminal justice and forensic science arenas since the late 1800s.

Criminal Identification Prior to the Use of Fingerprints

The impetus for the development of a reliable and accurate means of criminal identification came with the Technological Revolution, also known as the Second Industrial Revolution. This era ushered in technological advances (transportation,

electricity, modern manufacturing, and food processing) that brought more people into cities, thereby creating an atmosphere that nurtured the criminal element. As crime rates grew, police agencies recognized the need to document criminals and their record in order to identify recidivists. The first method of documentation came with the development of photography. Photography allowed for the creation of rogues galleries, posters for the police to reference, and mugshots. While the use of photography was an improvement, it certainly was not the solution to the problem of certain identity. A criminal could easily change their appearance by changing their hairstyle or shaving off facial hair. Additionally, police departments did not have standard procedures for photographing criminals. It was common to see men wearing hats and women wearing veils in mugshots.

Seeing the need for a new method of criminal identification, Alphonse Bertillon, a police clerk in Paris, developed a system of body measurements for personal identification, known as anthropometry. The thought was that specific body measurements of an individual would not change over time. As such, once a person's measurements were recorded, that individual would be identified with his or her record. Bertillon's method of anthropometry was put into use in 1882. At that time, anthropometry was viewed as a truly scientific method of criminal identification and the technique spread worldwide. However, as more agencies came to use the system and as files grew, it became obvious that anthropometry was failing. It was realized that different technicians took dissimilar measurements of the same person, thereby either determining that an individual was not in the record or that they were the wrong person.

In 1888, Sir Francis Galton was asked to deliver a lecture on the methods of personal identification for the Royal Institution of Great Britain. Galton's research led him to conclude that anthropometry was a failing system that would not survive the test of time. Anthropometry did not account for natural variability due to growth or aging, interdependence of body parts, and suffered from the inability of technicians to take the exact measurement. All these reasons could potentially cause missed or erroneous identifications. As a result, Galton set out to develop a method of personal identification based on fingerprints. Having determined the uniqueness and persistence of friction ridges, Galton knew that fingerprints could be used as an accurate and reliable means of personal identification. As a result, Galton devised a ten-print classification system based on three classes of fingerprint patterns, the arch, loop, and whorl. While Galton's classification system was too rudimentary for large collections of fingerprint cards, his establishment of the three classes of fingerprint patterns laid the foundation for superior methods to be developed.

Development of Friction Ridge Classification Systems

In order to achieve a workable ten-print classification system, fingerprint cards had to be classified into a formula that could differentiate large amounts of fingerprint cards. Each card could then be systematically filed according to its classification formula. A classified incoming ten-print card could be

searched in the filing system according to its formula. If the same formula was located, the incoming ten-print card was compared to each card assigned the same classification formula. If a match was not made, the incoming card would be filed with the same classification formula. If the comparison of the two cards resulted in the identification of a recidivist, then the police agency could add the applicable criminal charges to that person's rap sheet.

In addition to training police officers on the process of fingerprint comparison and identification, Juan Vucetich also developed his own ten-print fingerprint classification system. Vucetich's system divided the loop into two patterns (internal and external), added subcategories to further distinguish the patterns, incorporated ridge counts, and was expressed in the form of a ratio. In 1891, Vucetich successfully lobbied to have fingerprints replace anthropometry as a means of personal identification. Owing to the publication of his book, *Comparative Dactyloscopy*, in 1904, Vucetich's method of fingerprint classification received worldwide recognition.

Sir Richard Henry was also influenced by Galton's book. Realizing the need for a classification system that handles large amounts of data, Henry tasked two of his police officers in the Bengal District of India to create a workable ten-print fingerprint classification system. The two officers created a mathematical method that involved a pattern determination, ridge counts, and pattern tracings. In 1900, the Henry Classification System became the sole method of personal identification at Scotland Yard. Like Vucetich's classification system, the Henry system came to be used worldwide.

Numerous other ten-print classification systems were developed that were considered offshoots or extensions of the Henry or the Vucetich classification systems. For example, the Federal Bureau of Investigation (FBI) modified the Henry system to account for its large volume of fingerprint cards. In addition to ten-print classification systems, palm print classification systems, sole print, and single fingerprint classification systems were also developed.

Incorporation of Computers into the Science of Friction Ridge Identification

With technological advances in computer systems, friction ridge records were automated, thereby revolutionizing criminal identification. The establishment of automated fingerprint identification systems (AFIS) was based on the incorporation of the premises of friction ridge identification into the theoretical development of mathematical algorithms. Building on the science of uniqueness and persistence, software developers created computer algorithms that could extract the friction ridge paths and deviations and record this information as binary (zeros and ones) and then create mathematical maps of the extracted information. When a fingerprint or palm print card is entered into an AFIS, the resulting map is a series of numbers that have a direct relationship to the unique friction ridges contained therein. When a card is searched in an AFIS, the system compares the mathematical maps of the incoming card with the maps of the cards in the system and generates a list of potential candidates. AFIS also provide an invaluable service to forensic science and latent print examinations.

The technology developed for the extraction of minutiae of known cards allows for the encoding of minutiae in a latent print. The minutia within a latent print is encoded and, like a known print card, a mathematical map of the latent print is created. This mathematical map is searched in the database of known print cards, resulting in a list of potential candidates that a competently trained latent print examiner can manually compare and potentially make identifications to persons previously unknown.

Conclusion

Friction ridge impressions remain the primary method of reliable identification due to the principles that friction ridges are unique and persistent. Friction ridge identification and classification has a long history rooted in scientific research and empirical observations. From the 1600s to the present day, the study and use of friction ridge information has served to modernize the criminal justice system and forensic science. The use of friction ridge classification systems as a method of personal identification revolutionized the criminal justice system by creating a reliable and usable method of identification.

While classification systems were the work-horse of criminal identification for over 100 years, modern computing technologies have eliminated its use. Friction ridge impressions are now digitized. Current computer technologies allow for the application of mathematical algorithms to digitized friction ridge impressions in order to automatically recognize patterns, establish mathematical maps for every friction ridge impression based upon the type, location, and direction of minutiae, and the generation of a list of potential candidates as a match for a questioned print. This technology is not limited to known impressions taken under controlled conditions but also allows for the searching of latent prints from crime scenes in the digitized databases of known prints to establish previously unknown suspects.

Glossary

Eccrine sweat Is exuded by the eccrine glands which are located over most of the body but the highest concentration is on the palmar surfaces of the hands the soles of the feet and on the scalp.

Sebaceous sweat Is exuded by sebaceous glands which are located in various concentrations over most parts of the body with the exception of the palmar surfaces of the hands and the soles of the feet.

Unfortunately terminology in this area is not consistent. The 'undeveloped' deposit of chemicals on a surface delineating the shape of the ridges of a finger will be referred to here as a 'fingermark' or a 'latent fingerprint'. These are sometimes referred to as 'fingerprints', 'latent impressions', or 'latent fingermarks' or just, or sometimes simply as 'marks' or 'prints'.

When they are visible but have not been enhanced they are sometimes referred to as 'patent prints'.

When they have been rendered visible by chemical or physical means they will be referred to here as fingerprints.

If papillary ridges have left visible impressions in soft materials such as putty or wax they may be referred to as 'plastic prints'.

Record fingerprints of offenders or suspects taken by law enforcement agencies are commonly also referred to as 'prints' or sometimes '10 prints'.

Introduction

Development of latent fingerprints is a vital part of the forensic examination of crime scenes and produces important evidence for the effective prosecution of offenders. As indicated elsewhere in this encyclopedia, there are many techniques that may be used on the various types of surface encountered at crime scenes.

With the advent of DNA as a powerful crime-scene investigation tool, it has become increasingly important that fingerprint development techniques do not compromise other aspects of the examination of the crime scene.

In addition to detecting DNA in body fluids and latent fingerprints, the range of forensic examination procedures which may be necessary at typical crime scenes includes handwriting, indented impressions, ballistics, blood pattern analysis, explosive or drug detection, footwear impressions, examination for fibers, and other trace evidence and other specialisms.

In principle, the application of, for example, even fingerprint powder, or a solvent-based fingerprint reagent solution, could compromise many of these other forensic procedures. Sequence is therefore all important, with care it is usually possible to extract maximum value from all of the potential evidence. On rare occasions, one may have to compromise one type of evidence if it is judged that there is an interaction with treatment procedures and another should take precedence. This decision should be taken by a senior officer with responsibility for the investigation who has been fully briefed on the situation.

As various types of fingerprint development techniques detect several different classes of chemical compounds, there is considerable benefit in using several techniques one after the other. One therefore needs to consider which techniques are most appropriate for the surface; what sequence they will be applied in; and what other forensic examinations need to be incorporated into this overall protocol. Experts should work together to sequence examination procedures in a way that minimizes the loss of any type of forensic information. This can become quite a complex issue and the final sequence chosen will be dependent on a number of factors. These include the nature of the crime, the surfaces involved, any obvious contamination, the environmental conditions, and the time which has elapsed since the crime is believed to have been committed.

Sequencing protocols must be regularly reviewed as techniques change and in major cases a meeting between appropriate experts is advisable before starting any treatments. When new procedures are introduced, controlled experiments should be carried out to establish what interactions may be occurring and how any damaging effects can be minimized.

In addition to the obvious contamination by materials such as powders and the chemical effects of some developer solutions, it is also necessary to consider the effects of high-intensity visible or ultraviolet light, which will form part of many normal examination protocols for fingerprints.

Sequential Application of Fingerprint Development Techniques

The classes of compound present in natural latent fingerprints originating primarily from sebaceous and eccrine sweat glands are dealt with elsewhere in this encyclopedia. It also describes the types of reagent and the classes of compounds with which these reagents, in general terms, are believed to react. It also describes procedures for use when the deposit from a suspect's fingers may be wholly, or in part, some other known material such as blood or grease.

Usually, the investigator will know nothing about the chemical distribution of sweat constituents on the hands of a suspect. The application of several techniques targeting different classes of compound and used sequentially is very likely, therefore, to increase the chances of obtaining useful fingerprints. Even different reagents that target the same classes of compound will sometimes develop different fingerprints for

reasons, which are currently unclear. There is therefore merit, in important cases, in applying several techniques, if sequences can be established which minimize interference with subsequent processes.

Any sequence of techniques should therefore incorporate one or more methods which

- detect visible deposits on the surface; or impressions in soft materials such as wax or putty;
- detect eccrine sweat secretions, water, inorganic salts, amino acids, etc.
- detect sebaceous, fatty, or greasy deposits; or, if appropriate,
- detect known, or suspected, contaminants such as grease or blood.

Sometimes a subsequent technique will improve fingerprints developed by a previous method, sometimes it may develop completely new fingerprints; and sometimes it will destroy or degrade those already developed.

A process of logic, experimental trials, and operational trials has lead to sequences which have been generally agreed to maximize fingerprint yields. Flow charts have then been constructed for most types of surface. The first detailed recommendations for these sequences were published by the UK Home Office in 1986. These have been updated by the same team and researchers elsewhere have devised some variations to them.

Process Compatibility

Some techniques are almost completely compatible with one another if used in a particular sequence. An example of this is the use of Physical Developer after ninhydrin when treating paper. Ninhydrin reacts primarily with amino acids and if a suitable solvent system is used it has little or no effect on the heavier fats, waxes, or esters which are probably developed by the aqueous Physical Developer solution.

If Physical Developer solution were to be applied first, the aqueous constituent would wash out any amino acid present eliminating the possibility of subsequently detecting any fingerprints with ninhydrin.

Other interactions are less obvious and many are not well understood but have been established pragmatically. The use of DFO (1,8-diazafluoren-9-one) before ninhydrin yields significant numbers of extra fingerprints although both are reacting with amino acids. If, however, ninhydrin is used first virtually no extra fingerprints are found by subsequent treatment with DFO.

Other Factors to be Considered

When planning a sequence of fingerprint treatments some other issues need to be considered:

- What is the likely age of fingermarks of interest?
- What is known about environmental conditions to which the article has been subjected?
- What forensic examination procedures are also necessary?
- How important is the crime and what resources can be allocated to it?

Some fingerprint treatments will not develop fingermarks which have been wetted. Some are ineffective on older fingermarks and some conversely show some improvement with older fingermarks.

Some surfaces are so frequently touched by hands, for example door handles, handrails, and credit cards, that the surface has a very high background content of fingerprint constituents which will cause considerable problems for the detection of fresher fingerprints superimposed onto this background deposit. Some techniques are more likely to detect fresher fingerprints but none can be relied on as a method of estimation of the age of a fingerprint.

In serious crimes, the investigators will want to explore all possible sources of evidence. It must be appreciated, however, that a full implementation of all viable techniques to all exhibits in a case is rarely possible. Examining, for example, an entire house or business premises, in a kidnapping or terrorist case, could take many months of work. In reality, most examination procedures are a compromise.

In particular, examination using high-intensity light sources or lasers is very time-consuming and demanding on the examiner due to the number of possible excitation wavelengths and viewing filter combinations and the very faint fluorescence sometimes observed.

Photographic Recording of Developed Fingerprints

Since subsequent processes may degrade fingerprints revealed by a previous process developed fingerprints on exhibits must be photographed between each stage of a sequential examination. All the usual protocols for photographic evidence must be implemented. The image must be in sharp focus, taken perpendicular to the surface, incorporate an accurate scale and be captured at sufficiently high resolution for all identification purposes. Any digital imaging audit trail procedures, as required by local jurisdictions, must be complied with so that images may be presented in evidence at court.

The various development techniques result in different types of fingerprint and may require very different illumination and photographic procedures. If sequential processing is to be implemented routinely in a laboratory there are considerable advantages in establishing photographic workstations, which can be readily configured for the various types of image recording. Various light sources and filters will be needed and facilities for the use of various geometries of scattered, reflected, and transmitted light.

Fingerprints in Contaminants

If fingermarks are found at a scene of a violent crime where there is a considerable amount of blood, and it is believed that some articles have been handled by a bloody hand, special sequences may be more effective.

None of the techniques used for the development of fingerprints in blood is specific to blood so none can be used as presumptive tests for blood.

Similarly, at some crime scenes there may be obvious fatty or greasy contamination as for example in a kitchen or from the consumption of fast food. This may make conventional techniques such as powdering ineffective and inappropriate.

Examples of other fingerprint contamination may be oils and greases from industrial or automotive premises, accelerants at scenes of attempted arson, lubricants from condoms, and drugs or explosives, or their precursors, in drug- or terrorist-related crime. Some of these may require specialist advice from chemists on likely interactions with reagents.

Contaminated Exhibits

In many cases, articles may have been exposed to contamination subsequent to latent fingerprints being deposited. Examples include water either from rain or immersion, soaking in accelerants such as gasoline in failed attempts at arson or other materials.

Most agreed protocols cover situations where the article has been wetted, some other contamination may require specialist advice. Most accelerants do not prevent fingerprints being developed with amino acid reagents or physical developer.

Packaging and Handling of Evidence

It must be understood that any handling of exhibits from crime scenes, whether or not whilst wearing gloves, carries a serious risk of damaging latent fingerprints. Even superimposing, folding, or sliding surfaces together will have some effect on the fingerprint deposit, if it is on a smooth, non-porous, surface such as polythene.

Handling nonporous exhibits during treatment and photography through a sequence of processes, therefore, requires considerable care.

Porous surfaces such as paper absorb much of the deposit and handling is much less likely to cause damage.

Preliminary Procedures

If exhibits are wet in most cases it is advisable to allow to dry before any examination. Moderate temperature, usually no higher than 30 °C in a drying cabinet with a gentle forced draft may be used for such drying.

Investigators tasked with searching for fingerprints must have good eyesight and should be able to focus clearly on exhibits at a distance of 200 mm or less at low brightness levels. If necessary, spectacles must be worn to achieve sharp focus at this distance otherwise faint fluorescent fingerprints and some others may be missed.

Sequence Selection and Complex Exhibits

After drying there should be an initial assessment of the exhibit and a number of questions need to be asked which will assist in the selection of an appropriate sequence of treatments.

1. What materials are the main surfaces of the exhibit?
2. Which areas are most likely to bear fingerprints?

3. If the exhibit is made of more than one material can it easily be separated into constituent materials for separate treatment?
4. Are there indications that any fingermarks are likely to be contaminated with significant amounts of materials such as blood or grease which may influence the choice of reagent?
5. What colors are the surfaces to be treated?

If the article has more than one surface type which cannot easily be separated, for example a paper label on a wine bottle, methods of treating areas separately need to be considered, or a sequence of compatible processes established.

Initial Visual Examination – All Exhibits

The first step for most exhibits is a thorough visual examination with a source of uniform white light illumination. Reflective or textured surfaces may require manipulation of the light source to achieve high-angle and low-angle illumination which can considerably affect contrast and visibility of latent fingerprints.

There is some advantage in using relatively powerful sources but great care should be taken with light sources equipped with arc lamps. Some of these exceed the eye damage threshold, even for short period use, if looked at directly.

Visible fingerprints are most likely to be observed if:

1. The surface is particularly smooth.
2. Dirt or blood or some other colored contaminant has been deposited from the fingers.
3. The surface was dusty in which case the finger ridges may have removed dustleaving an image of the finger.
4. The surface is soft such as wax or putty and an impression of the ridges has been left.

Initial Fluorescence Examination – All Exhibits

Some latent fingerprints may fluoresce, as a result of either natural constituents or more likely contamination. In serious cases, a fluorescence examination should be carried out before chemical or physical treatments are applied. The background substrate color and fluorescence may influence the range of excitation and emission wavelengths, which are likely to be most effective.

In practice, relatively small numbers of fingermarks are usually detected during initial examination although on some surfaces such as polythene wrappers and bags; however, significant numbers may be detected if high-power sources such as lasers of appropriate wavelength are used. Currently, it would seem that solid state lasers emitting several watts of light at around 532 nm are among the most practical and effective for preliminary searching.

There is a greater possibility of fluorescent fingermarks being detected at certain types of crime scenes. In particular, in kitchens or other areas where food is prepared and there may be contamination with vegetable oils, greases, and fats. Similarly, at some types of industrial premises such as garages where mineral oils and greases may be common.

Many printing inks fluoresce so premises involved in, for example, forgery of currency may yield fluorescent fingerprints. Some of the precursors to drug and explosive manufacture also fluoresce so again fluorescence examination may be more productive in these cases but it will be necessary to use a number of excitation and viewing wavelengths as the characteristics of the chemicals will not normally be known.

Surface Compatibility and Performance

If we simply look at which processes will develop some fingerprints on a particular type of surface, we find that for smooth nonporous surfaces, powders, powder suspensions, small particle reagent, superglue, and vacuum metal deposition are all possible methods.

If one considers porous surfaces, ninhydrin, Indanedione, DFO, silver nitrate, and Physical Developer are possible methods.

Looking in more detail at the nature of the surface and examining the actual performance of these processes in substantial operational trials, significant variations are found.

The performance of dry powdering on low- or high-density polyethylene wrappings, a very commonly occurring substrate, for example, is generally poor. On the same surfaces, it has been found that superglue develops considerably more fingerprints than powders. Vacuum metal deposition will find even very old light fingermarks on some types of polythene but on recycled polythene bags, and some thick new low-density polythene the performance is poor.

Some of the recently developed powder suspension formulations based on special grades of iron oxide or titanium dioxide, however, perform well on many types of polythene surface.

Adhesive tapes can present particular problems, if they are stuck down we must decide whether to treat the back of the tape, before removing it and treating the adhesive side. If, for example, the tape is around a package of drugs in polythene wrappers it may be that a process such as superglue could be used to treat both surfaces before the tape is removed.

Some types of adhesive are incompatible with most Powder Suspension formulations so testing a small corner may be advisable before treating a whole batch of exhibits.

Operational Performance

Ultimately, the analysis of actual operational performance over hundreds or thousands of cases is the most effective way of determining optimum process selection and sequencing procedures.

Keeping records of the numbers of useful fingerprints developed on exhibits assists in improving future process selection but can also highlight problems with equipment, chemicals, or staff training. As packaging materials and technology change keeping accurate records can identify changes in substrates which require alternative methods or further research. Materials such as paper and more particularly plastics are evolving technologies which can significantly impact on fingerprint reagent performance.

Process Selection Charts

The sequences in the example charts in the section below have been developed by the UK Home Office. Large-scale laboratory trials were carried out on carefully constituted donor panels depositing depletion sequences of fingerprints repeatedly from the same finger. These were followed up by substantial operational trials in police forces of all major techniques. There are still, however, areas of uncertainty due to insufficient operational data.

The principle of these charts is that the most productive processes are on the main, wide routes but in important cases the additional techniques on the smaller side routes may be incorporated and sometime will lead to additional fingerprints being developed (Figures 1 and 2).

Recent indications are that some combined indandione–zinc salt formulations could be used in place of DFO and subsequent ninhydrin treatment, in the sequence for paper and cardboard with similar overall results.

Sequences have also been established for the following other classes of surface:

- Rough non-porous
- Plastic packaging material
- Vinyl, rubber, and leather
- Wood
- Metal
- Adhesive tapes
- Blood-contaminated surfaces

Difficult Surface Types

Some of the surfaces listed above present particular problems for fingerprint development and for some there are no methods with significant success rates. The particular reasons for such difficulties are indicated below:

Rough surfaces – the ability of the surface to retain sufficient information transfer from the fingerprint ridges. An additional problem, however, is that some techniques such as powdering will tend to enhance the surface topology rather than the fingerprint.

Vinyl (plasticised PVC) – particular problems are encountered with plasticized PVC, as used in imitation leathers for bags, etc. The plasticisers used are generally fatty materials which interfere with the development process.

Adhesive tapes – many fingerprints are developed on tapes but they can present problems because it is usually desirable to develop fingerprints on both sides of the tape. There are many backing materials used for tapes and different types of adhesive. Establishing a treatment protocol in such cases can be difficult; some techniques such as superglue or powder suspension may develop fingerprints on both sides of some tapes.

Adhesive tapes commonly have either acrylic or rubber-based adhesives which react very differently and sometimes adversely with methods such as powder suspensions. Testing on a small area before treating whole exhibits is recommended to determine whether background uptake is excessive.

Freezing or solvents may be used to assist separating adhesive tapes from substrates, although removal from porous

Figure 1 Process selection chart for smooth nonporous surfaces. From Bowman V (ed.) (Updated 2009) *Manual of Fingerprint Development Techniques*, 2nd edn. London: Home Office.

Figure 2 Process selection chart for Paper and Cardboard surfaces. From Kent T (ed.) (1998) *Manual of Fingerprint Development Techniques*, 2nd edn. London: Home Office.

surfaces such as paper is difficult. Solvents need to be used with care and most have some detrimental effects on some adhesives.

Metal Surfaces

Some specific metal items present problems for fingerprint detection and result in generally poor success rates. Firearms may be oily due to cleaning, or rusty, when secreted in damp conditions and much of the surface handled is often grooved or textured. These factors all mitigate against successful fingerprint development. Success rates on cartridge cases both unfired, and particularly fired, is low. This may be due to their limited size, method of handling, surface treatment, mechanical abrasion, and other factors.

Fabrics

There is no general technique for developing latent fingerprints on fabrics with a significant degree of success. Various workers have proposed osmium tetroxide, vacuum metal deposition, radioactive sulfur dioxide, and superglue. Some of these have shown some promise in laboratory experiments. Experimental results are usually significantly better on synthetic fabrics than natural fibers probably due to issues associated with absorption of sweat by the latter. Clothing items not in contact with the skin appear more likely to bear deposits which might be developed. Some ridge detail has been developed in a small number of cases by radioactive sulfur dioxide and a combination of the latter with a pretreatment with superglue. Trials by the UK Home Office in the 1980s indicated that a minimum thread density of around three threads per millimeter is necessary to have any chance of recording sufficient information for characteristics in a fingerprint to be resolved.

If hands or fingers are contaminated with dirt, blood or other materials there may be more chance of usable fingerprints being developed and there are significant numbers of cases of fingerprints in blood on fabrics being of operational value (e.g., Washington v. Hayden, 1995).

Skin

There is no generally accepted effective method for developing latent fingerprints on live or recently dead skin. There have been a number of trials of techniques for the detection of latent

fingerprints on cadavers, recently Trapecar and Balazic in Slovenia examined a number of methods. There have been similar trials in Canada, the United Kingdom, and Germany. Techniques tried have included lifting and transfer methods with silver plates and iodine, glossy paper and magnetic black powder, and direct powdering techniques. Treatment with superglue has also been tried. The few claimed successes are not well documented and in at least one case reports indicated that this was due to contamination of the suspect's hands with oil.

In principle, fingerprints in blood on skin could be potentially of value although there are no generally available reported cases.

Friction Ridge Skin Impression Evidence – Standards of Proof

C Champod, University of Lausanne, Lausanne, Switzerland

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Papillary surfaces are covered in fine lines, or 'ridges' arranged generally in patterns such as loops, whorls, and arches. The ridges form characteristics called minutiae, such as bifurcations, ridge endings (or combined minutiae), and also smaller features (pores, ridge edges, and structures). These detailed features are the consequence of a morphogenesis, so sensitive to outside influence that they are difficult to predict, unlike general patterns, in their position and their form. The variability is such that even monozygotic twins have distinguishable friction ridge skin in this respect.

Following a comparison between a mark (recovered for example in association with a crime) and a print (controlled impression associated with a suspect), suppose that the examiner observes agreement – within allowed tolerances given the flexibility of the skin, the distortion during the deposition process, etc. – between the mark and the print without any significant discrepancy. The question is then often expressed as follows: 'how many similarities are required to identify?' or 'what is the required sufficient agreement to conclude an individualization?'. Both terms 'identification' and 'individualization' are used here and hereinafter as synonymous.

The aim of this article is to try to address these questions of the 'standard of proof', by reviewing international views and practices. The perspective adopted here is essentially the one of the forensic practitioners dealing with friction ridge skin and not the perspective of the court or judiciary.

Historical Milestone

The first rule establishing the minimum number requirements for fingerprint identification can be attributed to the French Edmond Locard, in 1911–12 and officially published in 1914. He suggested a tripartite rule, which followed from the discovery of the use of pores when visible to help in the identification process (often referred to as *poroscopy*). Locard's rule can be summarized as follows:

1. If more than 12 concurring points are present and the fingerprint is sharp, then the certainty of identity is beyond debate. (The imperative requirement for the absence of significant differences is implicit.)
2. If there are 8–12 concurring points, then the case is borderline and the certainty of identity will depend on (a) the sharpness of the fingerprint; (b) the rarity of its type; (c) the presence of the center of the figure (core) and the triangle (delta) in the exploitable part of the print; (d) the presence of pores; (e) the perfect and obvious identity regarding the width of the papillary ridges and valleys, the direction of the lines, and the angular value of the bifurcations. In these instances, certainty can only be established after discussion of the case by at least two competent and experienced specialists.
3. If a limited number of characteristic points are present, the fingerprint cannot provide certainty for an identification, but only a presumption proportional to the number of points available and their clarity.

Locard based his tripartite rule on various sources of information: the discovery of poroscopy, the practice gathered by the identification bureaux around the world, and the early statistical models by Galton and Balthazard. This approach persists throughout the extensive writings of Locard. His considerations (principally the first two) were largely taken up by the most eminent dactyloscopists or criminalists of the first half of this century.

Current Views and Practice

On the fringe of the pragmatic view expressed above, the practice has led to various positions. The different positions that currently exist were not established without controversy after the views expressed by Locard.

Approach Based on a Predetermined Minimum Number of Minutiae

The majority of European examiners (and examiners from South America) have favored a purely quantitative approach, leaving qualitative aspects in the background, by fixing a numerical standard: a minimum number of minutiae necessary to establish identification. It is also referred to as the '*numerical standard*' approach or the '*empirical*' approach.

The numerical standard approach represents a lower limit; above this value, the identification is considered as beyond doubt, regardless of the type of minutiae that is found. The interpretation of the concept of numerical standard may vary from agency to agency; some positions are summarized in Table 1.

Despite the systematic use of a numerical standard, various countries (e.g., Greece, Holland, Israel, and Portugal) have developed methods to bypass the rigid number when certain features (visibility of pores, ridge structures, or rare combinations of minutiae) are observed in the comparison. The adoption of a range from 8 (or 10) to 12 points is a way to relax a rigid threshold. It is also reported in numerous countries that in some cases, an expert with more experience and a high standing in the profession can make an identification that does not meet the usual standard.

Approach Based on a Non-numerical Standard

Before the 1970s, American examiners followed Locard's view. As a result, the 12-point rule was generally respected, and below this threshold, qualitative factors in the comparison were taken into consideration. In 1970, a commission of experts

Table 1 Principal positions regarding numerical standards adopted in some countries

<i>Country(ies)</i>	<i>Numerical standard</i>	<i>Origin (when known) and specificity</i>
Italy	16–17	Probabilistic calculation by Balthazard dating back to 1911. The minimum standard is expressly mentioned from a jurisprudence referring to Balthazard's work. The jurisprudence dated back to 1954 but has been confirmed in 1959 and 1989
England and Wales (1924 to 2000), Scotland (before 2006), Australia (prior to 1941)	16	The origins of this standard (adopted by New Scotland Yard in 1924) dated back to an erroneous interpretation of a document published by Bertillon in 1912. The work by Balthazard had probably also played a role, as it was taken at face value in fingerprint training manuals. The numerical standard was virtually impossible to circumvent
Bosnia, Germany, Romania, Switzerland (before 2007)	8–12	In agreement with Locard, even though in practice, there is a clear tendency to respect a '12-point' rule
Albania, Australia (from 1942 to 1999), Belgium, England and Wales (before 1924), Finland, France, Hong Kong, Israel, Greece, Poland, Portugal, Romania, Slovenia, Spain, The Netherlands, Turkey, USA (before 1973), South American Countries	12	Number probably derived from the first rule of Locard (although Locard's writing stated 'more than 12'). Note that in numerous countries, mechanisms to bypass the rigid threshold are in place. For example in the Netherlands, a case of identification can be submitted with 10 minutiae if a committee of three examiners concurred to that conclusion
Czech Republic, Denmark	10	In Czech Republic, based in part on a statistical model developed by Jozefek in 1972 along with a survey of the relative occurrences of different types of minutiae
Russia, South Africa	7	According to a recent survey carried out by the IAI Standardization II committee

from the IAI was established to study the question of the relevance of a fixed numerical standard for decision making in this area. The work of this committee (for 'standardization') resulted in a number of articles and reports tracing the state of empirical and scientific knowledge. Apart from the fact that the justification of any number could not be based on statistical research pertaining to fingerprints, another powerful argument against any numerical standard derives from knowledge of the morphogenesis of the papillary lines. The development of papillary lines on corresponding surfaces is initiated (for the fingers) after 7 weeks of fetal life with the growth of volar pads on a papillary area. After 10 weeks, as the volar pads regress, primary ridges begin to grow in the dermis followed by secondary ridges. The various stresses involved in this process (regression of the volar pads, development of size, meeting of multiple development fronts) induce a highly variable formation of minutiae (in terms of type and positioning). Around week 25, the development of papillary lines is completed on the dermis and is projected onto the epidermis of the skin. The fact that the complete pattern is secured on the dermis explains the durability of the fingerprints. From that moment, a final differentiation occurs on the papillae, which dictates the form of pores and ridge edges. This final stage also produces a highly variable pattern (however, less reproducible from mark to mark). Hence, it is clearly not legitimate to reduce the fingerprint discriminative power to the minutiae as is suggested with any numerical standards. The number of specific features is much broader than minutiae alone. The nature of the papillary variability prevents the adoption of any predefined number of ridge characteristics necessary (without significant differences) for identification. Following such arguments, the following resolution was adopted by the IAI in

1973: "The International Association for Identification, based upon a 3-year study by its Standardisation Committee, hereby state that no valid basis exists for requiring a predetermined minimum number of friction ridge characteristics that must be present in two impressions in order to establish positive identification."

This resolution is also endorsed by practical observations as follows:

- Some minutiae are rare than others (for example, a double bifurcation in the periphery of the pattern is six times less frequent than two separate bifurcations). Hence, counting minutiae up to a predefined number without taking into account their relative and distinct values is not adequate.
- The absence of any minutiae, from a papillary surface is as relevant as their presence. It would be very exceptional to observe a core area or a delta area where the ridges do not display any minutiae.
- The pore structure and ridge edge structure can be used to discriminate and, when visible, contribute to the identification decision.

It is hence accepted that the concept of identification cannot be reduced to counting minutiae; each identification represents a specific set of circumstances and the identification value of concurring points between a mark and a print on a variety of conditions that automatically excludes any minimum standard. This approach is then also known as the 'holistic' approach or the 'non-numerical' approach.

In 1995, a conference meeting on fingerprint detection techniques and identification in Ne'Urim (Israel), unanimously approved a slight variation of the IAI 1973 resolution. The 1973 resolution was reassessed and reaffirmed

by the Standardization II committee in 2011 now reads: “*There currently exists no scientific basis for requiring a minimum amount of corresponding friction ridge detail information between two impressions to arrive at an opinion of single source attribution.*”

When an expert concludes an identification, he reaches a decision threshold (REFER TO ENTRY 197). This threshold may be a number of concurring points and, in addition to this quantitative element, consideration of other factors such as the rarity of the general pattern, the type of minutiae observed, the relative frequencies of these minutiae, or the visibility of ridge edges or pores. In this way, the identification process is a global assessment that balances both quantitative and qualitative aspects. The term *ridgeology* refers to this global assessment.

Various countries follow the IAI position, as indicated in Table 2.

It must be noted that the work done by the English committee has been a determinant in the various moves toward the late adoption of the IAI resolution in countries that applied a numerical standard. In 1989, a collaborative study among 130 fingerprint examiners in England and Wales was conducted by Evett and Williams. Each participant was sent ten mark/print comparisons (nine associations and one exclusion) and was asked to mark the number of concordant minutiae and to express an opinion with respect to the identification. No

erroneous identifications were reported. But, when examining genuine pairs of prints, examiners varied widely in the number of points of comparison they found. In the case of one print, it varied from 11 to 40 minutiae reported by examiners. In other words, some examiners would not have gone to court with this pair of impression, although most would have done so. An identical survey in Switzerland in 1997 led to analogous results.

These studies led to the following conclusions:

- The dogma adopted by some examiners that fingerprint identification is an ‘exact’ science is a misconception. The essence of science is inductive inference. Inference is a mental process that cannot be exact (or deductive). Fingerprint identification is scientific in that sense.
- The precision implied by any number (12, 16, etc.) is also a lure because of the high variability in feature selection between examiners. The determination of individual minutiae or features is highly dependent on training and experience but over all the quality of the mark itself.

As a means of achieving quality, adopting only a numerical standard is rather a poor instrument. The way forward is to concentrate on professional standards rather than on rules about numbers of minutiae. A scheme of quality management should be instituted, including training, certification testing, performance testing, file audits, and blind trials. This is part of the mandate of the FBI-sponsored *Scientific Working Group on Friction Ridge Analysis, Study and Technology* (SWGFAST) that proposes standards covering the above-mentioned quality components.

In relation to the standard of proof, the latest SWGFAST document: *Standards for Examining Friction Ridge Impressions and Resulting Conclusions* stresses three aspects:

- It is aligned with the 1973 IAI resolution through a statement saying that: “*The use of a fixed number of friction ridge features as a threshold for the establishment of an individualization is not scientifically supported.*”
- It is acknowledged that a conclusion is a decision (REFER TO ENTRY 197), for example, it states that “Individualization is the decision by an examiner that there are sufficient features in agreement to conclude that two areas of friction ridge impressions originated from the same source. Individualization of an impression to one source is the decision that the likelihood the impression was made by another (different) source is so remote that it is considered as a practical impossibility.”
- It proposed a sufficiency graph (Figure 1) that reflects the interplay between quality of the mark and quantity of minutiae observed during the analysis of the mark and its relation to the decision thresholds and levels of complexity based on a consensus of collective experience. The sufficiency graph is intended to illustrate the intellectual process involved with the examination of friction ridge detail and the ensuing decisions. It illustrates thresholds wherein examiners should recognize the need for, and provide, enhanced documentation supporting their conclusions.

Hence, it is important not to view the IAI 1973 resolution and its progeny as the promotion of a ‘laissez faire’ approach. It has

Table 2 Main positions and dates regarding the abandon of a numerical standard

Country(ies)	Origin (when known) and specificity
USA and Canada Norway	Since 1973, following the IAI resolution Other Scandinavian countries (Sweden, Finland) have now moved toward the abandonment of any numerical standard
England and Wales (from 2001), Scotland (from 2006)	In 1988, a committee was named by ACPO (Association of Chief Police Officers) and the Home Office to undertake a review of the origin and relevancy of the 16-point standard. Following this report, the abandonment of the numerical standard was recommended. It took more than 10 years to implement in England and Wales, longer in Scotland because of the McKie/Asbury case
Australia, New Zealand	In Australia, the move toward the abandonment started in some states and territories in 1992. The ‘12-point rule’ was nationally abandoned in favour of the IAI resolution in 1999
Switzerland (from 2007)	Taking advantage of the debate in the UK and Australia and following the Ne’Urim declaration, a committee was created in 1998 to manage the change toward a non-numerical practice. The change was approved by the Heads of fingerprint bureaux in 2007. The previous standard was 12 and has been kept as a Q/A filter to distinguish between simple and complex cases

Figure 1 Sufficiency graph showing the interplay between quality and quantity of minutiae observed during the analysis of the mark and its relation to the decision thresholds and levels of complexity. Adapted from Scientific Working Group on Friction Ridge Analysis Study and Technology (SWGFAST), Standards for Examining Friction Ridge Impressions and Resulting Conclusions, Ver. 1.0, http://www.swgfast.org/documents/examinations-conclusions/111026_Examinations-Conclusions_1.0.pdf

to be deployed within explicit guidelines defining quality and quantity.

Range of Possible Conclusions in the Field

Most contemporary experts refuse to give qualified opinions on friction ridge skin comparisons that do not meet the minimum requirements for an identification. From this standpoint, it is not encouraged to speak of association of strengths weaker than an individualization. It means that the last part of Locard's tripartite rule is not used in most countries. Only a few other countries are using such evidence as corroborative evidence. For example, in Belgium where there are between 8 and 12 points of agreement between a questioned fingermark and a fingerprint (without discrepancies), it is stated that 'the fingerprint could be the same as the fingermark being examined.' Therefore, apart from a few exceptions, Locard's third directive was totally forgotten as the use of dactyloscopy became widespread, thus giving this form of evidence its very distinctive character compared to other forms of impression evidence. In widespread practice, nowadays, the comparison between a mark and a print can be proof of identification or exclusion or it is declared as 'inconclusive,' without conveying any assessment of its evidential value. This is sometimes described as the 'positivity' of the field. In 1979, during the annual IAI conference, a resolution was approved prohibiting members from giving testimony on qualified identifications. This resolution was widely debated before being revised and accepted in 1980. The IAI experts then rejected the idea of using friction ridge skin evidence as corroborative evidence in the following terms (Resolution 1980–5, Amending Resolution 1979–7): "THEREFORE BE IT RESOLVED that any member, officer or certified latent print examiner who initiates or volunteers oral or written reports, or testimony of possible, probable or likely friction ridge identification, or who, when required in a judicial proceeding to provide such reports or testimony, does not qualify it with a

statement that the print in question could be that of someone else, shall be deemed to be engaged in conduct unbecoming such member. . . ."

Adopting such a policy means that in countries using numerical standards, for instance Italy, a fingerprint comparison with 16 concordant minutiae is an identification, whereas a comparison presenting only 15 points is not a probative evidence and should not be presented in court. Such a rule can easily result in difficult situations when, for example, a suspect is arrested and identified in one country on the basis of an identification with 12 points is to be judged in a neighboring country where 16 points are explicitly required.

Some authors and sources consider that the resolution voted by the IAI in 1980 – rejecting any testimony providing support in favor of identification or exclusion – is opposed to the scientific principles governing the interpretation of evidence in forensic science. They propose that it is erroneous to consider that evidence from friction ridge skin comparison is only a dichotomic form of proof, uniquely applicable to identifications or nonidentifications. The interpretation cannot be so drastic, so clear-cut; there is an increasing scale of strength from exclusion to identification.

In fact, there is no logical reason to suppress these levels between exclusion and identification. Each piece of evidence is relevant if it tends to make the matter at issue more or less probable than otherwise. The refusal of qualified opinions is only a policy decision.

Often, probabilities have been excluded from the field arguing that each portion of a friction ridge skin impression, no matter how small, can only have come from one finger. It is the individuality of the papillary impression that is at question and not the individuality of the skin surface that produced it. The transfer of material in criminalistics, as defined by Locard, logically implies, by definition, a loss of information. For friction ridge skin, this loss may be of two types: quantitative (due to the limited size of the trace) and qualitative (blurring, bad definition, loss of pore details, etc.). The concept

encapsulates a continuum of values in that a feature may have a discriminative value ranging from very low to very high.

Locard's third directive is fundamental and permits evidence from friction ridge skin to be on the same level as other types of impression evidence (or more generally forensic evidence). Some will no doubt argue that judges expect such evidence to be univocal and without compromise. This idea is false. It is obvious that any judge will prefer indisputable forms of proof but would also wish to be informed of any evidence that can lead closer to the truth. Much useful evidence should not be kept out of the courts on decision of technicians; it is up to the court to decide whether the evidence adduced is relevant.

The perceived absence of extensive statistical data on fingerprint individuality can be viewed as the main reason to prevent giving qualified opinions. Statistical data could make experts feel more comfortable in this area and make statements based on sound data obtained from significant samples. The Standardization II committee indeed recognized "the potential value that a validated probability model would have when expressing what is currently viewed as an 'inconclusive' conclusion." Following its committee report, the IAI 1979/80 resolutions have been recently rescinded (Resolution 2010–18).

Recently, Neumann et al. have shown that very high weights of evidence (appropriately measured using a likelihood ratio) could be obtained from comparisons between marks and prints possessing a limited number of corresponding minutiae. When mark and prints are originating from the same source, an average likelihood ratio of 10^5 is obtained for comparison involving only 4 minutiae. This strongly shows the feasibility of evaluating evidence from friction ridge skin in a probabilistic way. It is possible to obtain, with some specific minutiae on a surface (or in the absence of minutiae on a large papillary surface), probability figures that exceed the value proposed in other forensic fields (e.g., DNA), even with fewer than 12 minutiae.

The Move Toward Quality

Occurrences of Errors

Analysis of results from proficiency testing or from casework clearly indicates that error is possible and that some examiners do not reach adequate quality standards. The publications of S. Cole and J. Koehler are important here. The two most notorious cases of misattribution are the case against Brandon Mayfield (USA) and the case against Shirley McKie and David Asbury (Scotland). The largest controlled study by Ulery et al. involved 17 121 presentations to a pool of examiners ($N=169$). It led to six cases of false identifications – a false positive rate of 0.2%.

But the evaluation of the standard of proof (or the quality of the evidence) cannot be limited to the examination of proficiency testing programs. Indeed, the corrective actions taken in an agency, following an erroneous identification, are far better indicators of quality than the report of errors (or successes). A global assessment of quality is then needed. The inquiry reports associated with the Mayfield case and the McKie/Asbury show the importance of a quality management system.

Total Quality Management

A total quality management system, based for example on the European Foundation for Quality Management (EFQM) model, can be recommended and is the basis of the most recent changes in the fingerprint practice. The various aspects of such a system are illustrated in [Figure 2](#), the program is divided here into three parts: examiners, processes, and products. For each category, the quality management scheme must specify the needs and objectives, along with the quality indicators used to monitor the system and the corrective actions available. Audits (internal and independent) permit the claims to be checked regularly.

Figure 2 Outline of a total quality management system for a service dealing with friction ridge skin examinations.

In such a general context, proficiency testing must be regarded as only one block of the building. The value of identifications based on the examination of friction ridge skin will be better assessed on the basis of a strict quality assurance program. A large number of laboratories have now implemented quality assurance programs. A convergence is currently seen toward the adoption of the EN ISO/IEC 17020 or 17025 standards. In 2009, the European Council issued a decision (EU Council Framework Decision 2009/905/JHA) requiring all forensic laboratories dealing with friction ridge skin impressions to gain accreditation under EN ISO/IEC 17025 by 2018.

Conclusion

Locard proposed the basic concepts determining the value of fingerprint evidence. Locard's opinions were enlightening and, above all, the most topical. From this early perspective, a large number of countries adopted a fixed (sometimes negotiable) standard in the form of a minimum number of matching minutiae required in order to conclude to an identification. This is now known as the numerical (or empirical) approach. Even if some practitioners rely on minimum numbers, they do not escape, thanks to the arbitrary limit, from the quality issues because, depending on the examiners, the interpretation of the number of minutiae in a comparison may vary to a large extent.

However, the detailed analysis of the factors contributing to the discriminating power of friction ridge skin shows that there is no scientific argument in favor of any predefined number of minutiae (in the absence of discordance) in order to pronounce an identification. Every comparison bears its own specificity, which refrains from defining a priori the amount or volume of information needed for the identification. The decision is then taken on a case-by-case basis by the expert. The approach is called holistic (or non-numeric). It forces the field to rely on experience, professionalism, and integrity of the examiners.

Finally, following this description of fingerprint practices, what is the standard of proof? Definitely, the standard is not a predefined number of minutiae. Indeed, insisting dogmatically on any particular minimum number of points is not an effective way of insuring quality. But the holistic approach should not promote a culture of 'laissez faire' without boundaries. The recent document by SWGFAST provides essential limits to the practitioner. The way forward goes also hand in hand with the adoption of a scheme of quality management

dealing with the various aspects of education and training, laboratory procedures, and audits.

Concerning the possibility of giving corroborative opinions based on such evidence (in favor or otherwise of an individualization), it seems that from a scientific point of view, there is no argument to justify the so-called 'positivity' of the field. Nothing opposes the use of such evidence as corroborative evidence in the same way as other forensic evidence.

Glossary

Automatic fingerprint recognition (AFR) and automatic fingerprint identification systems (AFIS) These systems encode fingerprint images, generally by locating the positions, relative angles, and ridge counts between fingerprint minutiae or characteristics. This enables database searching for likely matches.

CCD and CMOS These are two types of solid-state digital imaging sensors with subtly different characteristics and are used in modern digital cameras.

Eccrine sweat This is exuded by the eccrine glands which are located over most of the body, but the highest concentration is on the palmar surfaces of the hands, the soles of the feet, and the scalp.

Minutiae, characteristics, or Galton details These are ridge endings and bifurcations, or forks.

Sebaceous sweat This is exuded by sebaceous glands which are located in various densities over most parts of the body with the exception of the palmar surfaces of the hands and the soles of the feet.

Introduction

Fingerprints are widely associated with the identification of offenders in many types of major and minor crimes although in recent years DNA trace evidence has made an increasingly important and high-profile contribution to criminal identifications.

This increasing use of DNA analysis of swabs from crime scenes, while important, has not diminished the need for fingerprint examination. Generally, DNA analysis is still significantly more expensive, and does not necessarily prove actual contact between suspect and object. DNA is, however, capable of providing crucial identification evidence in some circumstances when there are no suitable surfaces available for fingerprint examination. The two techniques are therefore complementary, although generally in most countries fingerprints currently still produce more identifications.

Increased usage of forensic databases and crime-linking and data analysis tools allows combinations of fingerprints, DNA, footwear, toolmarks, and other data such as modus operandi to link multiple crime scenes with offenders.

Efficient and effective visualization, referred to more commonly as development or enhancement, of latent fingerprints, is therefore a vital part of the forensic examination of a crime scene and of exhibits removed from crime scenes. It is important that it is carried out in a careful and methodical manner with due regard to preserving DNA and other evidence.

Origins of Fingerprint Deposits

The papillary ridges of the fingers, the palms, and the soles of the feet have located in them rows of sweat pores linked to eccrine sweat glands and they exude aqueous eccrine sweat in varying amounts. The fingers and palms are naturally in intermittent contact with other parts of the body, due to normal human behavior patterns, including the hair and face of an individual. These areas have traces of oily or greasy sebaceous sweat originating from sebaceous glands which are found in greatest abundance on the face and the scalp, some of this sebaceous sweat transfers to the fingers and palms resulting

in these surfaces bearing a mixture of sebaceous and eccrine sweat. There may also be material from apocrine glands, which are restricted to the axillae, areola, and genitoanal regions. Although the division of aqueous and fatty deposit into clearly separate phases, or droplets, may often be observed microscopically, it is likely that some of the deposit is actually in the form of an emulsion.

This mixture, or emulsion, does not have any particular, fixed distribution and will contain hundreds of compounds in various concentrations, which depend on the climatic conditions, an individual's biochemistry, habits, lifestyle, and recent behavior such as hand washing.

Sometimes, the fingers and hands of a suspect may be contaminated with materials which do not have a bodily origin such as foodstuffs, soaps, cosmetics, industrial chemicals, and other materials from the environment.

When the ridges of the fingers, palms, or feet touch a surface, they will transfer some of this mixture of chemicals to that surface – an example of Locard's exchange principle that 'every contact leaves a trace.' Depending on the pressure and direction of contact, and the nature of the surface, some of the deposit may be in the form of a pattern reproducing the ridges on the skin surface.

These deposits are not usually in simple continuous lines but on smooth nonporous surfaces are usually in the form of a distribution of retracted droplets of various sizes on a thin film which may be only a few molecules thick. On porous surfaces, such as paper, wicking action results in the more mobile constituents being absorbed into the surface (Figures 1 and 2).

Fingermarks may also contain solid matter such as dead skin cells shed from the hands and dust from the environment.

At some crime scenes, there may be gross contamination resulting in most of the fingerprint deposit being blood, grease, oil, drugs, explosives, and so on.

Fingerprint Patterns, Characteristics, and Detail

When fingermarks are to be developed or enhanced, in order that identifications may be made for judicial purposes, they

must contain sufficient detail for comparison with record prints. This usually necessitates sufficient area of two or more of the following levels of detail:

1. The overall ridge flow pattern, namely loop, arch, whorl, and so on
2. Characteristics, also known as Galton detail or minutiae, essentially the patterns left by papillary ridge terminations and bifurcations
3. The so-called third-level details which may encompass finer detail of pore distribution, ridge width, ridge shape, and minor papillary ridge irregularities

The development technique chosen may affect the amount, or quality, of information produced at these three levels.

Imaging of Developed Fingerprints

Until the end of the twentieth century, fingerprints would normally be photographed using film cameras of various

formats. The resulting negatives would then be used to produce 'life-size' hard copy prints on black-and-white photographic paper. Usually, the procedure was to produce such prints so that the ridges were black and the inter ridge spaces white; for detailed comparison and court presentation work, five times life-size enlargements would usually be printed.

Now, imaging, or recording, is virtually entirely carried out using digital cameras or scanners. The capture systems may then download the digital image into an automatic fingerprint identification system (AFIS); when necessary, life-size, or enlarged, prints can be produced, normally still in black-and-white.

Image quality is important and in digital systems is controlled by a number of factors:

1. the quality of the charged coupled device (CCD) or complementary metal-oxide semiconductor (CMOS) imaging chip;
2. the effective pixel count per millimeter in the image plane;
3. the quality of the optical system; and
4. correct exposure and focus.

Lossy image compression techniques will also reduce the amount of information in the image and algorithms must be carefully assessed before adoption.

Image scale is also important, different AFIS may tolerate varying amounts of distortion, but images should generally be captured within a linear tolerance of 1% or 2% to maximize hit rates.

It is good practice always to incorporate a scale into captured images unless fixed-focus camera systems are used.

Development or Visualization of Latent Fingerprints

Many fingerprints are still retrieved at crime scenes with simple powdering techniques, which have changed little over several decades. There are, however, an increasing number of more sophisticated and sensitive processes which may sometimes be used at crime scenes, but which are more commonly applied in specialist fingerprint enhancement laboratories to which articles are sent. Studies in some law enforcement agencies have shown that half, or more, of the operationally useful fingerprints are now produced in such laboratories.

The wide range of chemicals which are likely to be present in fingermarks provides scope for many different chemical and physical reactions to be exploited. The amounts of material present, however, are very small, usually nanogram quantities, and some individuals leave exceptionally small amounts of deposit. Developing such latent fingerprints is a difficult technical challenge and presents problems which are at the extremes of current methods of detection.

Not only do we want to detect the components on a variety of surfaces but we need to map them so that we produce a high-quality image of their distribution on a surface.

Latent Fingerprint Chemical Constituents

While many studies have been carried out into the chemical constitution of sebaceous and eccrine sweat there are rather

fewer of the actual deposits left by a finger on a surface. This is due partly to the technical challenges in analyzing the sub-nanogram quantities of components. One significant early review was carried out by Cuthbertson in the 1960s; he also carried out some early measurements of chloride content. More recently, Croxton in 2008 analyzed the content of actual fingerprints rather than sweat.

From our knowledge of sebaceous and eccrine sweat, we would expect some of the materials in Table 1 to be in a fingerprint.

Amounts of deposit vary widely within and between donors. A significant proportion of the original mass of some eccrine-rich fingermarks is actually thought to be water, which on a nonporous surface may evaporate over the first few hours or days depending on ambient temperature. Trapping of the aqueous component in a fatty matrix or emulsion may be responsible for some observed differences in evaporation rates. On a porous surface such as paper, this water will assist in the diffusion of some of the constituents into the surface. Studies in the early 1970s by Thomas indicated that on nonporous surfaces,

many fingerprints lost significant volume by evaporation over the first few days after deposition (Figure 3).

Operational Methods of Visualizing Fingerprints

There are published papers on hundreds of chemical reagents and other techniques which are claimed to visualize latent fingerprints. Operational trials and experience have shown, however, that only around 15 basic techniques produce significant numbers of usable fingerprints under realistic crime scene conditions. We will not therefore include here the wide spectrum of possible techniques but rather focus on those which have so far been developed to the stage of being operationally of significant value and implemented successfully.

Some reagents have been used in dozens, or even hundreds, of formulations and it is important that optimum formulations and treatment protocols are established and adhered to. Much of the research effort expended has been in refining formulations and procedures to optimize techniques. Subtle changes in solvent systems, humidity, or heating regimes can make substantial differences to the numbers of fingerprints developed with some methods.

When new techniques are discovered, it is important that they are compared against existing techniques in a thorough manner using realistic sample fingermarks from a range of donors.

Some researchers have used 'groomed' or 'enhanced' fingermarks by touching the nose or forehead before depositing test prints. This procedure cannot be relied upon to give an indication of operational performance. Recent research has shown that the lipid content of such groomed fingerprints may be many times that of a typical operational fingerprint (Table 2).

Fingerprint development or enhancement techniques fall into five broad categories:

- (i) Chemical reagents which react with a known constituent or class of constituents of latent fingerprints stoichiometrically; with these techniques, the intensity of the reaction

Table 1 Latent fingerprint constituents – after Cuthbertson

Gland type	Inorganic constituents	Organic constituents
Eccrine	Chlorides	Amino acids
	Sodium	Urea
	Potassium	Lactic acid
	Ammonia	Sugars
	Sulfates	Creatinine
	Phosphates	Choline
Apocrine	Iron	Uric acid
		Proteins
		Carbohydrates
		Cholesterol
Sebaceous	–	Fatty acids
		Glycerides
		Hydrocarbons
		Alcohols

is quantitative and directly proportional to the amounts of the specific compounds in the latent fingerprint.

- (ii) Chemical or physical agents which are absorbed, or adhere to, or undergo some other nonspecific interaction with a class of compounds in the fingermark. Generally speaking, the reaction is approximately proportional to the amount of deposit present.
- (iii) Chemical reagents which rely on a component of the fingermark to catalyze a chain reaction, which leads to a non-linear enhancement or amplification of the fingerprint.
- (iv) Chemical or physical agents which are designed to target known contaminants such as blood or grease and used if these are seen on the surface under examination.
- (v) Optical techniques which rely on the absorption, scattering, polarization, or fluorescence effects on radiation, which we can speak of as light, but which may be anywhere in the spectrum from the far ultraviolet (200 nm) to near the infrared (2 μ m).

Some developmental procedures are actually multistep, involving development and enhancement techniques where the initial reaction produces a low visibility product, which is then enhanced by a further step or steps.

Choice of Technique

Generally, the most significant factor influencing the choice of process will be the surface to be examined. Smooth, solid, essentially nonporous surfaces such as glass retain a 'sticky' latent fingerprint residue on the surface which may be detected by careful application of powders, although there are other techniques which may be more sensitive.

Porous surfaces such as paper or cardboard absorb varying amounts of the sebaceous and eccrine deposit and visualization may be best achieved by more specific chromogenic reagents, for example, those which react with amino acids.

Some plastic surfaces present problems which are midway between the nonporous and porous classes.

Some surfaces which are frequently handled can prove difficult for the investigator due to the buildup over time of a background level of the constituents of eccrine and sebaceous sweat; examples are door handles and credit cards.

Other factors which can affect choice of process are:

- (i) Facilities available.
- (ii) Importance of the case.
- (iii) Possible age of the fingerprints of interest – days, weeks, or months.
- (iv) Ambient conditions and the likely exposure to sun and rain and contamination from the environment.
- (v) Presence of contaminants in the fingerprint such as grease or blood which may make up a significant part of the deposit.
- (vi) The need to carry out other forensic examinations including sampling for DNA, explosives, fibers, drugs, and so on. Documents may require examination of handwriting or indented writing. Some fingerprint development techniques can interfere with some of these procedures, so the correct sequence of examination is important.

Packaging and Handling of Evidence

It must be understood that any handling of exhibits from crime scenes, whether or not while wearing gloves, carries a risk of damaging latent fingerprints. Even superimposing, folding, or sliding surfaces together will have some effect on the fingerprint deposit if it is on a smooth, nonporous surface such as polythene or a weapon such as a gun or knife. Porous surfaces such as paper absorb much of the deposit into the surface, so careful handling is much less likely to cause damage. Hard, smooth items should preferably be tied, or wired down into boxes, and never carried in evidence bags.

Operational Fingerprint Development Processes

The processes that will be described here include most of the methods currently considered to be most productive and operationally effective. Brief details of each process, and where known, some details of the possible reactions and materials detected are given. Other similar variants are also listed but detailed formulations are available elsewhere, so no specific formulations are given here.

Most are reagents for the usual constituents of latent fingerprints where the material on the fingers is primarily eccrine and sebaceous sweat.

Four additional reagents – Amido Black, Acid Yellow 1, Acid Violet 17, and Solvent Black 3 – are included, of which the first three are used for enhancing blood and the last for greases or fats from nonsweat sources. These are used when there is an indication that any fingerprints present may be significantly contaminated with such materials.

Optical techniques, which may be used before or after chemical treatments, are described separately.

Health and Safety Procedures

Some constituents of some reagent formulations present significant health and safety issues, including high flammability and toxicity by ingestion, by inhalation, or in some cases by

skin absorption, for example, methanol. Safe working practices have been developed for most reagents but competent expert advice must be sought before implementing any chemical enhancement technique.

There are potentially serious eye safety considerations with many light sources used for fluorescence examination and even some used for white light examination. Hardwick and others published the only significant study of these sources in 1990; users should never look into the beam of such sources.

Local regulations and standard operating procedures must be complied with.

1, 8-Diazafluoren-9-one (DFO)

1, 8-Diazafluoren-9-one (DFO) is a very effective reagent for amino acids in fingermarks and was proposed in 1990 by Grigg, although the chemical had been synthesized by CIBA in 1950. It reacts with amino acids from eccrine sweat, usually producing only a faintly pink-colored visible reaction product. The reaction product is, however, strongly fluorescent and, overall, the method is more sensitive than ninhydrin if exhibits are examined and photographed with the correct combination of excitation and viewing wavelengths.

The absorption and emission maxima are close with only a small Stoke's shift. Exhibits are usually best illuminated between 525 and 550 nm and viewed or photographed with a short-wave cutoff filter transmitting above about 560 nm.

Articles are dipped into a solution containing DFO, acetic acid, and a carrier solvent mixture. They are then heated in a dry oven at 100 °C for 20 min. As with most amino acid reagents, the precise combination of solvents dramatically affects the operational success rates observed.

DFO is generally used on the same types of porous substrates as ninhydrin, primarily paper and cardboard. It does not develop all of the fingermarks detected by the latter, so additional fingerprints may be produced by subsequent treatment with ninhydrin.

If humidified conditions are used during the heating of DFO-treated articles, no fingerprints are detected (cf. ninhydrin).

As amino acids are soluble in water, reagents such as DFO, ninhydrin, or indanedione are ineffective on surfaces which have been wetted or exposed to very high humidities.

DFO is not usually used at scenes of crime as it is difficult to generate sufficient heat in a room to produce an acceptable rate of fingermark development although local heating can be used for small areas. It is similar in performance to some indanedione formulations which incorporate zinc and is widely used.

Gun Bluing and Similar Metal-Toning Treatments

Latent fingerprints usually have a significant proportion of sebaceous, or oily or fatty, components. This can provide a protective layer on some surfaces such as metals, and chemical toning techniques can be used to discolor the areas not protected by the fingerprints, thus rendering the latter visible. A number of commercial gun-bluing solutions have been used on cartridge cases and some other surfaces with variable success. Similar methods using selenic acid or sulfides or other

metal toners or etching solutions have been reported and some are in operational use.

Iodine Vapor Fuming

The observation that iodine fumes could be used to both detect handwriting alterations and develop latent fingerprints was reported by Coulier in 1863; methods of application were described in the literature in 1891 and 1912.

A temporary faint purple to brown stain is created which fades in minutes or hours although it may be enhanced, or fixed, by a number of techniques including starch powder or alpha-naphthoflavone applied in solution. Various iodine fuming chambers or 'guns' have been used to treat paper or other porous or nonporous exhibits. It is most effective on fresh fingerprints that are hours or days old.

The vapor process is little used now partly due to the intensely corrosive and toxic nature of iodine but also because several techniques have generally surpassed it in terms of sensitivity.

The mechanism is not fully understood and may involve more than one reaction. It appears to be readily reversible and it has been proposed that it may be a reaction with unsaturated fats, a physical absorption by lipids, or a reaction with aqueous components.

Indanedione

In the late 1990s, the reaction of fingermark amino acids with indanedione was explored by researchers at the University of Pennsylvania. It is similar in application to DFO and reacts to form a faintly colored, but fluorescent, product. The original formulations were found to be operationally less effective than DFO during substantial trials in 2002 in the United Kingdom by West Midlands Police.

If treated subsequently with zinc, or other heavy metal-toning solution, a substantial increase in fluorescence is achieved with a resulting increase in numbers of fingerprints of value detected.

Recently, incorporation of zinc salts into the indanedione primary reagent solution, by Stoilovic and others in Australia, and use as a single treatment, has produced a very effective reagent with a performance comparable to DFO followed by ninhydrin.

The treatment protocol is similar to ninhydrin or DFO, involving briefly dipping exhibits in the solution followed by heating either in an oven or a press; the former is more controllable. Various solvent formulations have been proposed and as with most amino acid reagents they have a critical effect on operational performance.

Some workers have recorded improved results in a humidified oven if the ambient humidity is low but more research is probably needed.

There are a number of published spectra for reaction with specific amino acids but there are few data on optimum excitation and emission for typical fingerprints although most workers illuminate in the green/yellow region and observe in the orange/red.

It is now quite widely used as an alternative to DFO and, as a single treatment, can replace the DFO–ninhydrin combination.

Ninhydrin

Ninhydrin was proposed by Oden in the 1950s as a reagent for detecting fingerprints. After the publication of the Crown formulation in 1969, and others, it became the most widely used reagent on paper, cardboard, and some other porous materials such as raw smooth wood. It is chromogenic, producing a purple reaction, Ruhmann's Purple, with some amino acids. Various formulations have been developed with a range of solvents from flammable petroleum ether and chlorofluorocarbons to the more recently introduced hydrofluoroethers. The solvent system and pH significantly affect the operational performance, and the most effective formulations incorporate acetic acid. Where written documents are to be processed, it is important to consider the effects of solvents and possible ink running and loss of indented impressions.

Articles are dipped into a solution containing ninhydrin, acetic acid, and the carrier solvent mixture and allowed to dry. For best results, they should then be heated at 80 °C for 3–4 min at 65% relative humidity (Figure 4).

The developed purple-colored fingerprints can be easily photographed in white light but a green filter is often used to improve contrast on some colored backgrounds.

Ninhydrin can be very effectively used at scenes of crime, with the same formulation being brushed onto the surfaces. Sealing the room and raising the temperature with domestic heaters will assist fingerprint development but it may take several days as it is difficult to control the temperature and humidity.

When ninhydrin develops fingermarks on dark non-fluorescent backgrounds, or when the background is a very similar color to the fingerprint, zinc chloride toning solution can be applied and the exhibit gently heated to produce fluorescent fingerprints, which can then be photographed.

Figure 4 Document with a number of ninhydrin-developed fingerprints. Courtesy: UK Home Office.

Physical Developer

This is essentially a stabilized silver-plating solution, which may be used on porous surfaces such as paper, cardboard, and wood. Jonkers and others at the Philips Eindhoven laboratory published details of a solution for depositing silver onto printed circuit boards. Morris and others at the UK AWRE laboratory found that some long-lasting and persistent constituents of latent fingerprints would trigger the deposition of silver microspherules although there is still speculation as to which materials these are. It was found that as a fingerprint reagent it was capable of developing fingermarks on articles which have been soaked in water or exposed to rain.

It is a relatively slow multibath treatment but it has shown considerable operational success on old and wetted paper items. Items must be soaked in distilled water and washed in dilute acids such as maleic, to reduce background reaction, before carefully controlled treatment with the silver solution.

The reagent is an aqueous solution of silver nitrate containing an Fe(II)/Fe(III) redox couple and two detergents. Subsequently, excess silver salts must be thoroughly washed out before drying. All glassware must be extremely clean to prevent triggering of the silver deposition.

The developed fingerprints are a light to medium gray in color and can be recorded using conventional photography. The exact reaction mechanism is unknown; it was thought that it was developing some of the heavier fats and waxes although it is possible that trapped chloride ions in sebaceous deposits could play a part.

Fingerprints developed by the physical developer may be enhanced by conversion to a radioactive sulfide and autoradiography, or x-ray mapping in an electron beam instrument.

Powders

Powders are probably the oldest and most common techniques for the enhancement of latent fingerprints; Forgeot and others were experimenting with different powders in the latter part of the nineteenth century. In the early decades of the twentieth century, many powder combinations were in use including toxic mercury and chalk mixtures (hydrargyrum–cum–creta), and oxides of lead, and many other less toxic materials such as carbon and natural materials such as *Lycopodium* and dragon's blood.

Many types of powders and brushes have been used over the intervening years and hundreds of combinations are commercially available.

Powders with a flat, flake-like, structure, such as milled aluminum or brass, for example molybdenum disulfide, are among the more sensitive and are generally quite effective at developing fingerprints on smooth, clean surfaces. Stearic acid or similar fats are commonly added during the milling process of aluminum and it is thought that this may contribute to the sensitivity of the technique. A milled iron flake powder was developed at the University of Swansea in the late 1990s for application with a magnetic 'wand' and is quite effective particularly on unplasticised polyvinyl chloride window frames. Other magnetic powders based on iron or nickel have been available for many years.

Aluminum and some other flake powders can be applied effectively with glass fiber or fine synthetic brushes. Fine black carbon-based powders are best applied with soft synthetic or animal hair brushes and trials have indicated that some of the fine carbon black powders are of similar sensitivity to flake powders.

Flake powders are usually lifted with transparent adhesive tape or commercial tacky “lifters,” for scanning or photography, this assists with the removal of background and simplifies recording. Other powders may be lifted or photographed in situ.

If sensitive flake powders are used on surfaces which are dirty or contaminated, sometimes too much will deposit obscuring any fingerprints. In such cases, granular black or white powders may be more suitable, even if slightly less sensitive. Rough or grained surfaces may sometimes be treated using iron, cobalt, or nickel-based powders used with a magnetic applicator although other processes may be more suitable.

Many fluorescent powders have been proposed for use with suitable light sources, and is referred to in several books on fingerprinting techniques, including that by Bridges in 1942, many of which are currently marketed. Although these may improve contrast between fingerprint and multicolored surfaces, some fluorescent powders are less sensitive than established nonfluorescent powders, probably due to their physical shape and size.

Powders may be used on surfaces which have been wetted, but only after the articles have been thoroughly dried at temperatures not exceeding 30 °C.

The performance of powders generally deteriorates with the age of the latent fingerprint but occasionally very old ones are detected by this means; they are therefore not a reliable indicator of time since a latent fingerprint was deposited.

Powder Suspensions

Although commonly referred to as suspensions, they are actually rather viscous mixtures of fine nontoxic powders such as iron oxide, carbon black, or titanium dioxide with a surfactant and various proportions of water. Bratton and others reported the use of a viscous mixture of black fingerprint powder and detergent for the development of fingermarks on the adhesive side of tapes in the mid-1990s.

Several such powder suspensions or pastes were proposed or marketed under various names including ‘Sticky-Side Powder™’ for use on the adhesive side of adhesive tapes. They were usually based on mixtures of black fingerprint powder with surfactant and water. A fairly thick paste of the powder is applied to the adhesive side of the tape, either by dipping or careful brushing. The solution is left in contact with the tape for 10–15 s and then washed off under running water, resulting in gray to black images, which can be recorded using conventional photography.

Subsequently, it has been found that such suspensions can be very effective on many smooth surfaces but particle size and shape are critical, as is the surfactant. Formulations using white and other colored or fluorescent powders have also been developed.

The process is becoming more widely used although further research is needed. They are easily applied in a laboratory

where exhibits can be washed in a sink but more difficult at crime scenes where they cause gross contamination and require considerable cleanup.

Small Particle Reagent

Small particle reagent was developed by Morris and others at the Aldermaston Weapons Research Establishments in the United Kingdom in 1978, the original formulation being based on gray molybdenum disulfide flake in water and surfactant. Concentrations of powder and surfactant were much lower than the more recently developed powder suspensions, so the reagent has a very low viscosity, similar to water. It is most effectively applied in a tank in which the powder is agitated prior to immersion of the object to be treated. The main surface of interest should be uppermost, on which the powder is allowed to settle, then excess powder is carefully rinsed off and the exhibit allowed to dry (Figure 5).

The grade of molybdenum disulphide is critical to its effectiveness. The Forensic Science Service in the United Kingdom promoted a spray version of the molybdenum disulphide version for use on wet cars, but it proved to be far less sensitive than the immersion process. Other researchers have developed white and fluorescent versions although in tests none has matched the original formulation for sensitivity.

Basic Violet 3 (Gentian Violet, Crystal Violet, CI 42555)

The use of aniline dyes for staining latent fingerprints was patented in the United States by Bock in 1917. A very effective formulation of Basic Violet 3 in phenol and ethanol solution was reported by the Italian Police in the late 1960s and has been used widely since the 1970s for the detection of latent fingerprints on the adhesive side of tapes. The reagent stains latent fingerprints purple and is usually applied by floating the tape on the surface of the solution with the adhesive side down. The tape is then washed in running water and dried. Fingerprints may then be photographed if the tape is light in color.

Figure 5 Fingermarks on a polystyrene cup developed with small particle reagent. Courtesy: UK Home Office.

Increasing usage of black electrical tapes on improvised explosive devices resulted in the development of a technique by Kent in 1978 for transferring the image onto fixed, washed, and dried photographic paper.

Low concentrations of Basic Violet 3 in fingerprint deposits will fluoresce in the far red if illuminated with yellow light.

Concerns over the toxicity of phenol by skin absorption have resulted in the development of a number of surfactant-based formulations omitting phenol. Some of these, particularly those using aerosol OT surfactant, show similar or better performance than the original. Recent developments of powder suspensions have, however, reduced the usage of dye techniques on adhesive tapes.

Superglue

The reaction of the vapor of ethyl or methyl cyanoacrylate with latent fingerprint deposits appears to have been noticed independently in Japan in around 1977, and in subsequent years in Canada and the United Kingdom, as the Japanese discovery was not initially revealed in the West.

Fingermarks exposed to the vapor were observed to produce a white deposit of cyanoacrylate polymer, usually after a few hours although sometimes extended development times of up to 24 h were used. Kendall and others reported heating superglue to speed up the reaction in the early 1980s (Figure 6).

Research by the UK Home Office established that by raising the humidity to 80% and the glue temperature to around 120 °C, fingerprints development was much more rapid and even older fingermarks would often develop in about 20 min. These conditions were recommended in the Home Office Fingerprint Manual of 1986 after microscopic studies and extensive trials (Figure 7).

Elevation of the relative humidity to around 80% causes sodium chloride in latent fingerprints to take up water, forming minute droplets along the lines of the deposit. Other components in the deposit may be responsible for raising the pH and accelerating the reaction, which usually results in a white growth of 'cotton wool' or 'noodle-like' growth of microscopically fine fibers. Use of an aluminum container reduces the amount of cyanoacrylate, which polymerizes in the source vessel.

Figure 6 Plastic molding with a number of superglue-developed fingerprints. Courtesy: UK Home Office.

On many surfaces, the white deposit may simply be photographed by scattered light but enhancement with fluorescent dyes such as Rhodamine 6G was soon introduced by Menzel and others in 1983 with methanol as a solvent, and has been widely used since although methanol should not be used due to its high toxicity. In 1986, the UK Home Office introduced the use of Basic Yellow 40 in ethanol as a nontoxic extremely efficient fluorescent dye for superglue-developed fingerprints. Brief immersion followed by gentle washing in water and drying results in strongly fluorescent fingerprints which may be illuminated in the blue region and observed in the yellow region, making photography easier on some surfaces.

The exact nature of the initiation and growth process of the polycyanoacrylate is not well understood although several studies have examined possible mechanisms and initiators.

The technique has been exploited widely since its discovery with several types of commercial cabinets available, and several incorporating facilities to raise the humidity. It is a quick simple method for many types of plastic film, plastic moldings, and polystyrene foam and has been used on a wide range of other surfaces experimentally and operationally.

Fingermark development is also observed under vacuum conditions and was first reported by Watkins in 1989, although the fingerprints developed do not show the characteristic 'noodle-like' growth, instead appearing as transparent glassy deposits which must then be enhanced with fluorescent dyes. It is generally agreed that this method is significantly less effective operationally as it has lower sensitivity with less uptake of dyes by the glassy deposits.

Several researchers, including Weaver in 1993, have attempted, so far unsuccessfully, to synthesize a modified cyanoacrylate which is inherently fluorescent.

Vacuum Metal Deposition

This method is derived from a commercial process for coating surfaces with thin layers of metal or dielectric materials. It is carried out under vacuum and involves the thermal evaporation of metals onto the surface to be examined.

Figure 7 Electron micrograph of superglue-developed fingerprints. Courtesy: UK Home Office.

The process had been known for many years to be susceptible to fingerprint contamination, and in industry, degreasing procedures are used before glass or plastic items are coated with materials such as aluminum or chrome.

In 1964, Tolansky suggested that this technique might be of operational forensic value; in 1968, Theys in France proposed its use for detection of fingerprints on paper. Hambley, in 1972 at Royal Holloway College, investigated the behavior of a wide range of single metal and metal combinations. The use of gold followed by cadmium was then developed by Kent in the UK Home Office initially as an operational technique for the fingerprint treatment of low-density polyethylene bags and wrappings; due to health and safety concerns, cadmium was replaced by zinc in the early 1980s (Figure 8).

It is extremely sensitive, sometimes too sensitive, and it has been shown that a monolayer of fatty acid can sometimes inhibit metal film growth. It has found fingerprints in cases where polythene wrappings have been underwater for long periods of time.

The object being treated is placed inside a large metal chamber, most of the air is evacuated reducing the pressure to between 2 and 4×10^{-4} mbar, and metals are evaporated sequentially onto the surface. The generally recommended method for fingerprints on polythene is the evaporation of a few milligrams of gold from a molybdenum filament heated to a bright yellow to white heat, at about 1000°C . A larger quantity of zinc is then evaporated from a molybdenum trough heated to a dull red at about 450°C ; the evaporated zinc deposits onto available gold nuclei and produces a gray image. Any developed fingerprints may appear as positive or negative images as the film growth is modified by surface contamination. The differential rates of film growth on substrate and fingerprint may be due to differences in gold nuclei size or penetration of the nuclei into the surface.

The process has been used very effectively operationally on polythene packaging. Experiments to apply the method on fabrics in the 1980s yielded some results with fresh fingerprints on finely woven fabrics but no operational successes during limited trials.

Silver can be used as a single metal treatment and may be effective on some types of cling film. Coating of some types of recycled plastics is difficult and some other techniques such as powder suspensions are more effective.

Development of Contaminated Fingermarks

Fingermarks in Blood

If a fingerprint on a porous surfaces looks as if it may consist of some eccrine sweat and some blood, amino acid reagents such as ninhydrin, DFO, and indanedione may be very effective. On nonporous surfaces, Acid Black, Acid Yellow 7, or Acid Violet 17 are most effective for detection of the bloody component.

Many tests and dyes for blood have been reported in the literature.

Acid Black 1 (Amido Black)

Acid Black 1 or Amido Black, CI 20470, is a dye which has long been used to stain protein. It will bind to proteins present in blood or other body fluids to give a blue-black stain. It will not detect normal eccrine and sebaceous sweat components of natural fingerprints and is therefore used when it is believed that the fingerprint consists largely or wholly of blood. Porous surfaces will take up the dye and often cause a high background coloration and alternative reagents may be preferable on such surfaces. It is usually used in an aqueous ethanolic solution but the bloody deposits must first be “fixed” either by heating or more commonly by application of solutions such as sulphosalicylic acid. This fixing prevents diffusion of the deposit during the staining stage and was reported by Faragher and others in 1981.

Fingerprints developed by Amido Black are dark blue-black in color and can be recorded using conventional photography.

Acid Yellow 7

This has been introduced more recently as an extremely sensitive technique to enhance fingerprints in blood but is a fluorogenic reagent which must be examined and photographed using an appropriate combination of excitation and viewing filters. It is recommended in the UK Home Office *Fingerprint Manual*, which suggests excitation in the green region, between 445 and 478 nm and recording the emission in the green-yellow region between 485 and 500 nm.

Fingermarks in Grease

Light fingerprints contaminated with grease from, for example foodstuffs, or as may be encountered in engineering workshops, may be developed with conventional processes such as fingerprint powders. It is recommended that small areas be tested first, and if gross contamination resulting in substantial take-up on the background is observed, the following alternative reagents may prove more effective.

Solvent Black 3 (Sudan Black 3)

Proposed as a fingerprint reagent by Mitsui and others in 1980, this method was investigated for developing latent fingerprints on surfaces such as polythene by Pounds in the UK Forensic Science Service but it was found to be less effective than established techniques. It was subsequently found to be of value in circumstances where there is a significant amount of fatty or greasy contamination. These surfaces can be difficult to treat with powders due to a high uptake across the surface.

Figure 9 Fingermarks in greasy contamination on food packaging developed with Solvent Black 3. Courtesy: UK Home Office.

Treatment with fat dyes can selectively indicate areas of thicker or thinner deposit sometimes revealing fingerprints (Figure 9).

In the laboratory, articles are usually immersed in an ethanolic solution of Solvent Black 3 followed by careful washing. A less flammable methoxypropanol (propylene glycol methyl ether) formulation has been proposed by the UK Home Office for use at crime scenes.

Solvent Black 3 has been suggested by Castello of the University of Valencia as a method of enhancing lip prints.

Optical Techniques

Visual examination with white light

Visual examination in white light has the advantage of being nondestructive with regard to both the fingerprint deposit and any other forensic evidence. Sometimes on smooth surfaces, visible fingerprints will be seen that can be photographed by means of reflected or scattered light.

It is important to experiment with the angles of illumination and observation. In particular, reflective or textured surfaces may require manipulation of the light source to achieve high- and low-angle illumination, which can considerably affect contrast and visibility of latent fingerprints. On porous surfaces, only contaminated fingerprints are likely to be seen visually.

Sometimes on badly contaminated surfaces, such as where there is a substantial deposit of grease from foodstuffs and such application of chemical or physical development techniques may actually obscure fingerprints which can be seen visually.

Epitaxial white light visual examination

On some surfaces, illumination and viewing coaxially, usually normal to the surface, can be effective in detecting untreated fingerprints (Figure 10).

Viewing devices have been marketed which incorporate white light sources in combination with prisms or other types of beam splitter to carry out such epitaxial, or coaxial illumination, and observation. This technique is probably most useful on smooth, flat, shiny surfaces when latent fingerprint ridges may appear dark against a light background; the method is, however, not widely used.

Figure 10 Schematic showing optical path for epitaxial viewing.

Reflected short-wave ultraviolet imaging

Reflected short-wave ultraviolet imaging (RUVIS) was proposed in the 1980s and several types of prototype or commercial systems have been built. Surface reflection characteristics in the ultraviolet can be very different to those in the normal visible spectrum. The shorter wavelengths are scattered more than in the visible spectrum so that, for example, superglue-developed fingerprints can often be easily separated from the background with good contrast and no use of fluorescent dyes.

As the eye is not capable of imaging UV light, special image converter tubes are used, usually in conjunction with 254 nm mercury light sources. This wavelength is potentially damaging for eyes and skin and full protective equipment is essential.

Some fresh latent fingerprints on smooth surfaces are visible by short UV scattering by careful manipulation of illumination angle. After a few days, this effect is dramatically reduced and generally powdering or other techniques are more productive.

Fluorescence examination

Although there were some earlier experiments using ultraviolet lamps to attempt to detect latent fingerprints, the most significant step was that by Duff and Menzel in 1976. They reported seeing latent fingerprints in their laboratory using a high-power argon ion laser operating at 488 or 514.5 nm. Such lasers were expensive and the procedure was time-consuming and not very productive, but this triggered the development of a variety of detection and enhancement systems based on fluorescent processes.

Work in the early 1980s in the United Kingdom, Australia, and Canada resulted in the introduction of various high-power nonlaser light sources. All these used focused arc lamps and dichroic filter combinations, giving relatively narrow bands of visible light which could be used to excite fluorescence. These were considerably cheaper and more portable than the argon ion lasers of the day and were capable of producing illumination over a wider wavelength range. Several light sources available today for forensic fluorescent examination are based on this technology although recent developments in light-emitting diode (LED) and solid-state lasers are also utilized in some systems.

The requirements of fluorescent examination are that the light source should provide a relatively uniform divergent or parallel beam capable of illuminating a few hundred square centimeters with a relatively narrow range of wavelengths, perhaps 20–200 nm bandwidth depending on the application. Effective light power in the incident beam, not lamp power consumption, should be between 0.5 and 5 W in the band of interest; higher powers can be used but great care must be taken not to melt or damage substrates. Commonly, wavelength selection from arc lamp sources is by insertion of dichroic filters in the path of the lamp. Delivery of light to the surface under examination is usually by liquid light guide for higher powered systems although lasers will normally use optical fibers and LED sources may be simply handheld devices.

Fluorescent compounds have unique excitation and emission spectra and can require widely different excitation and viewing wavelengths. Absorption of a photon of short wavelength radiation usually results in an almost immediate release of a photon of lower energy, and hence longer wavelength: Stoke's law q.v.

Light sources must have sharp cut-offs at the longer wavelength end of the power band and be used with viewing filters or camera filters which have a sharp cut-on close to the light source cut-off and transmit less than one part in 10^4 of the 'excitation' range of wavelengths (Figures 11 and 12).

Fluorescence examination for fingerprints falls into two major categories:

- (i) Initial examination of untreated, or latent, fingerprints for any inherent fluorescence which may be of natural or foreign origin.
- (ii) The enhancement of development fingerprints that have been treated with reagents which may or may not produce a fluorescent product.

Fluorescence – initial examination

This requires slow methodical careful examination under dark-room conditions by staff with good close vision and who are fully dark-adapted. Usually, any fluorescence of untreated fingerprints is very faint and easily missed. Most natural

components of latent fingerprints do not fluoresce. There are three amino acids which fluoresce in the visible region: tryptophan, tyrosine, and phenylalanine. Some workers have reported measurable levels of phenylalanine in fingerprint deposits. It is extremely unlikely, however, that these materials are being detected during initial fluorescence examination procedures.

It may be more likely that when untreated fingerprints are found by fluorescence, they are contaminated with fluorescent materials from the environment. No reliable data are available in this area but many greases, creams, cosmetics, industrial chemicals, and even environmental dust, among others fluoresce.

Operationally, it has been found that with suitable powerful light sources and correct viewing and camera filters, fluorescent fingerprints can be more frequently found on some polythene packaging, in kitchens and industrial premises, at illicit drug factories, in printing industry premises, and so on.

A difficulty with effective initial fluorescence examination is that as the chemicals which may be detected are unknown, there is no single combination of excitation and viewing filter which will detect all materials. The wrong combination of wavelengths will not result in visible fluorescence. In a major investigation, it is therefore necessary to use a number of light source and filter combinations. Comprehensive detection can only be achieved by sequential examination with a range of excitation wavelengths from the violet to the yellow region that should be used with appropriate viewing filters. There is some evidence that excitation around 530 nm is particularly productive. This may be due in part to the fact that it is above the primary excitation range for most artificial brighteners which are incorporated into many man-made materials such as paper, plastic, and paint.

Fluorescence – enhancement of developed fingerprints

Several of the established fingerprint development processes either produce a fluorescent product, such as DFO, or have supplementary treatment steps which produce a fluorescent

Figure 11 Schematic showing absorption and emission bands of a fluorescent material and the relative light source and viewing filter characteristics necessary for detection of fluorescence.

Figure 12 Schematic showing effect of correct viewing filter for the detection of fluorescence.

Figure 13 Superglue-developed fingerprints which have been dyed with Basic Yellow 40 and photographed by fluorescence. Courtesy: UK Home Office.

result, such as superglue-enhanced with Basic Yellow 40, or indanedione with zinc salts.

Fluorescent viewing and photography of such fingerprints can be very effective if the correct excitation and emission wavelengths are used (Figure 13).

Fluorescence examination can also be used to enhance some nonfluorescent developed fingerprints by causing the background to fluoresce, for example, ninhydrin-developed fingerprints on colored paper surfaces may sometimes be enhanced in this way.

Ultraviolet and infrared fluorescence and imaging

UV fluorescence between 300 and 400 nm excited by UV at 277 nm was reported by Okhi in 1970. Long-wave and short-wave fluorescence were investigated and used by Creer in the UK Metropolitan Police in the late 1980s and 1990s. Some fingerprints on smooth papers were detected by background fluorescence of the paper with local absorption of UV by the fingerprints.

Some natural constituents, such as phenylalanine, or contaminants, such as greases, may absorb light in the near ultraviolet and emit in the blue part of the spectrum. Some may absorb in the ultraviolet and emit in the ultraviolet, requiring specialist UV-sensitive imaging devices as used for reflected ultraviolet imaging, RUVIS, see earlier.

Many inks and some oils absorb in the yellow-red part of the spectrum and emit in the infrared region. To detect fingerprints in such contamination requires the use of infrared-sensitive viewing devices or cameras. Such procedures are not currently common although there is increasing interest in imaging outside of the visible part of the spectrum, referred to variously as chemical imaging, or hyper-spectral or multi-spectral imaging.

Silicon-based CCD and CMOS cameras have inherent sensitivity in the near infrared but many have internal blocking, which can make them unsuitable unless they can be removed.

Other Reported Techniques

The following techniques are not in widespread use but have either been reported to be worthy of investigation or have been used, or are used, in special circumstances, or are currently under development and assessment.

Radioactive sulfur dioxide has been used to detect and image latent fingerprints on adhesive tape and experimentally to image them on some types of finely woven fabrics. First reported by Grant in 1963 and investigated at AERE Harwell, small quantities of a sulfur-containing compound are ignited and the exhibits after exposure are autoradiographed.

The use of bromine, iodine, or iodine monochloride incorporating radioactive isotopes was investigated in similar treatment protocols to the use of sulfur dioxide.

Various electron beam imaging methods are being investigated.

Modified physical developers and multimetal deposition techniques have been investigated by several workers including Saunders at Los Alamos, Cantu of the US Secret Service, Becue of the University of Lausanne, and others.

Nanoparticle methods in solution are being investigated by various research groups.

The use of sulfur nitride polymerization is a recent development by Kelly and King at the University of Loughborough.

Electrostatic imaging methods for revealing fingerprint-induced corrosion on metals, such as cartridge cases, are under investigation.

Silver nitrate solution, reported in the 1890s, reacts with chloride in the fingerprint to form insoluble silver chloride, which goes black on exposure to light. This was used for many years on porous surfaces such as paper and raw wood but has generally been superseded by amino acid reagents such as ninhydrin and physical developer.

Osmium or ruthenium tetroxide have been used either in the vapor phases or in solution to develop latent fingerprints by their reaction with unsaturated fats, which results in gray deposits of the reduced metals. These have been used experimentally on fabrics but with limited success.

Dimethylaminocinnamaldehyde in solution was investigated by Morris and others at AWRE Aldermaston for fingerprints on paper but it proved less successful than ninhydrin. It has recently been used by a number of workers for developing fingerprints on thermal printing papers and has been applied in the vapor phase.

Many authors have referred to heating paper at temperatures between 150 and 200 °C, which will eventually often result in fingermarks becoming visible as the deposit initiates local carbonization resulting in brown fingerprints. This method is not used operationally due to availability of other methods.

Glossary

Blank cartridge Blanks are cartridges containing gunpowder but no bullet or shot.

Captive bolt pistol This term describes a device used for stunning animals prior to slaughter. Discharge of a blank

cartridge drives a metal rod ('bolt') initially positioned inside the barrel out of the muzzle against the animal's forehead in order to induce sudden unconsciousness.

Stud gun An industrial tool designated for firing metal nails or studs into wood, concrete, or steel.

Introduction

A livestock stunner ('humane killer,' slaughterer's gun, livestock narcotic device, captive-bolt gun) is used in abattoirs, butcher's shops, and farms to induce immediate unconsciousness before slaughtering animals. The first stunning devices were constructed at the beginning of the twentieth century. They consisted of a simple barrel with a heavy flange or trumpet-like muzzle end, which had to be placed against the animal's forehead; an ordinary cartridge carrying a bullet was inserted into the opposite end of the barrel and discharged by striking the firing pin with a wooden hammer. Since the bullets frequently caused accidental injuries, from the 1920s and 1930s onward an increasing number of butchers turned to the safer 'captive-bolt' stunners. Nevertheless, only until recently in several countries such as Britain were improved models of free-bullet slaughtering pistols being used (for instance, the Green-er's Humane Cattle Killer).

Captive-Bolt Humane Killers

This type of slaughterer's gun consists of a cylindrical metal tube that serves as a guide for an inlying steel rod ('bolt'), which has a diameter of 7–12 mm (Figure 1). The bolt is driven by the explosion gases of a blank cartridge and propelled a few centimeters beyond the muzzle. The report is less loud than in shots from real guns.

The distal end of the steel rod is usually excavated (conically grooved) so that its front acts like a sharp-edged circular punching tool. The initial velocity of the bolt is rather low ($\sim 40\text{--}45\text{ ms}^{-1}$) compared with hand guns ($\sim 300\text{ ms}^{-1}$).

After firing, in most models, the bolt is automatically drawn back into the barrel either by compressed air or by rubber bushes and/or by a withdrawal spring. This rebound mechanism also prevents the bolt from becoming a free projectile unless the device is manipulated before firing (e.g., by removal of the rubber bush and withdrawal spring). Therefore, injuries can only be inflicted from a short distance of less than the propelled bolt's length ($<10\text{ cm}$).

The muzzle plane of the captive-bolt humane killer may show two or four openings arranged symmetrically beside the central hole serving as outlets for the explosion gases, which are partly drained off through diverging smoke conduits (Figure 2). This applies to the German Kerner type and some other models (e.g., Dick, Rekord, Ursus, and Kuchen). The number and location of the additional openings essentially determines the smoke soiling pattern in contact or close-range shots (paired or clover leaf-shaped soot depositions). Recently, a captive-bolt pistol with four lateral gas outlets (brand mark 'Humanitas') has been introduced on the market. In other models (for instance, the Cash and the Temple Cox slaughtering guns from the UK or the Schermer type from Germany), the soot emerges only along the bolt's guide so that the blackening from gunpowder residue may either resemble a ring of dirt encircling the entrance hole or cover a greater

Figure 1 Two makes of captive-bolt stunners. Top: Schermer type (mod. ME, cal. 10 × 11 mm, diameter of the bolt 12 mm); bottom: Kerner type (mod. 289, cal. 9 × 17 mm, diameter of the bolt 11 mm).

Figure 2 Muzzle end of two captive-bolt stunners. Left: Kerner type with two opposite openings (outlets for the explosion gases; arrows); right: Schermer type without additional smoke conduits.

area in circumferential distribution. The extent of smoke deposition depends on the propellant (black or smokeless powder) and on the strength of the charge used.

The blank cartridges (Figure 3) are loaded with smokeless or black powder and differ with regard to the caliber fitting into the chamber of the respective model (e.g., 0.22 in, 9 × 17 mm, 10 × 11 mm). The strength of ammunition varies depending on the animal to be slaughtered. The manufacturers offer several sizes of charge distinguished by color markings on the base of the cartridge case (with the strongest ones meant for heavy bulls painted black or red).

Injuries from Captive-Bolt Narcotic Devices

When stunning meat stock, the muzzle has to be placed tightly against the forehead so that the whole length of the bolt enters the cranial cavity. Analogous to the veterinary application, in most human victims, the weapon is fired in contact with the skin. Nevertheless, the entrance wounds lack all the classical signs of contact shots as known from conventional firearms.

Figure 3 Blank ammunition for captive-bolt stunners. Cattle-killing cartridges RWS 9 × 17 mm; the case mouth is sealed by crimping the metal and inserting a wax plug. The strength of the cartridge is designated by a green color marking on the base of the case ('green' meant for small cattle and pigs).

There is no muzzle imprint and no stellate splitting because the skin is not ballooned out by expanding combustion gases, which follow a free bullet but not a captive bolt. Consequently, only little, if any, soot is found in the depth of the entrance hole. The excavated distal end of the bolt causes a sharp-edged circular punch lesion with the diameter of the entrance hole being a little smaller than that of the bolt due to the skin's elasticity. If the shot is fired at an oblique angle, there is a unilateral sickle-shaped beveling of the corium indicating the bolt's direction.

Humane killers with two or four smoke outlets on the muzzle end produce a characteristic soot pattern consisting of roundish or elliptic zones of blackening arranged in congruity with the respective openings. Variations in shape and location of these foulings point to an oblique holding of the instrument. In noncontact shots the smoke deposits become larger, but less intensive, with increasing distance and finally disappear. Interposed hair or garments covering the entry site may prevent the skin being blackened at all. As mentioned above, other kinds of captive-bolt instruments do not have any additional smoke conduits; in such cases, the entrance wound is surrounded by a ring or a circumferential area of powder soiling. If the soot was wiped off in the course of surgical treatment, the affected skin areas tend to dry up producing a brownish discoloration.

The typical entry sites are regions of the body where only a thin layer of soft tissue overlies flat bones (forehead, temple, parietal, and occipital region). When the bolt enters the skull, it produces a round hole, which is sharp-edged ('clean-cut') on the outer table and beveled-out ('cratered') on the inner table. The external aspect of the entrance hole almost exactly reflects the cross section of the bolt, whereas the inner diameter of the bone defect is much larger. In shots fired at an acute angle, the entrance in the bone is oval-shaped and sometimes accompanied by semicircular frame-like fracture lines.

Figure 4 (a) Distal end of the captive-bolt in a Kerner-type slaughtering gun; the steel bolt is conically grooved. (b) Punched-out piece of skin from the depth of the intracranial wound path ('skin imprimatum'). (c) Histological section of a skin imprimatum showing a bacterial colony and blackish powder residues (arrow). Hematoxylin and eosin stain.

Owing to the limited length of the bolt, in shots to the head, no exit wound is to be expected. Of course, there is no bullet left at the end of the wound track. Because of the bolt's punching function, the impact surface is forced into the depth of the brain. The punched-out skin and bone are thrust inward and left there as a so-called 'imprimatum.' The skin is nearly always a component of the imprimatum (Figure 4) and must be regarded as bacterially contaminated and therefore infectious. Apart from the skin and the bone imprimatum, other material from outside such as pieces of hairs and textiles may be pushed into the wound path. Despite its low velocity, the bolt causes a remarkably wide wound channel owing to the large cross section and the excavated front; hemorrhage results from mechanical tissue damage with disruption of vessels. In contrast to the extensive local traumatization, indirect lesions such as secondary skull fractures are rare.

Fatalities from Humane Killers

Most of the fatal injuries from livestock narcotic devices are suicides, which account for 85% of the published statistical figures. Though the number of accidents and homicides is comparatively small, the possibility of such incidents has to be kept in mind. In the German language literature, there are reports on more than a dozen homicide cases with a high percentage of female victims. In contrast to this, the great majority of suicides are males, most of them butchers or farmers, familiar with slaughtering guns. The frequency curve attains its peak in the fifth and sixth decade of life.

The most common sites of suicidal entrance wounds are in decreasing order of occurrence: the forehead (Figure 5), the temple, the parietal and occipital region (Figure 6), the

Figure 5 Contact entrance wound from a Kerner-type captive-bolt livestock stunner in the central forehead of a suicide. The initially circular skin hole is partly held together by a surgical stitch. The entrance wound is accompanied by two roundish soot deposits corresponding to the openings of the smoke conduits.

precordium, and the mouth. Some individuals use two or more different methods when committing suicide, for example, by placing a noose around the neck before shooting themselves in the head with a livestock stunner. Some authors have even described suicide by repeated cranial shots from captive-bolt humane killers. Such observations prove that bolt injuries of the brain are not necessarily followed by immediate or persistent unconsciousness, if the bolt does not strike a vital area of the brain. Despite severe damage to the frontal and/or temporal lobes, the individual may be capable of reloading the humane killer and firing a second time.

In fatal cases, the survival period varies widely and may last up to several weeks or even months. The mortality has decreased, thanks to the great progress made in neurosurgery and

Figure 6 (Continued)

intensive care, but in general the prognosis is still rather poor, though recent clinical studies report survival rates of more than 50%. In addition to extensive brain damage and intracranial bleeding from lacerated vessels, inflammatory complications such as pyogenic encephal meningitis or a cerebral abscess may be the cause of a delayed fatal outcome.

Suicidal injuries from captive-bolt humane killers are almost always contact shots. In most cases, the shooting device is found close to the deceased. The hand holding the muzzle end often reveals soot on the radial surface of the index finger

and on the ulnar surface of the thumb. Other visible soot deposits may be transferred to the hands in the course of loading. In suicides, firing again after the first shot, the hands and the weapon are usually soiled with blood pouring from the entrance wound in the course of reloading.

The relatively small number of homicide cases is probably due to the limited length of the bolt, which does not allow shots from a distance of more than a few centimeters. Most victims are, therefore, either defenseless or unaware of an attack.

Figure 6 (a) Suicide victim (47-year-old male butcher) lying on a sofa in prone position. The bolt of the slaughterer's gun (Schermer type) had got stuck within the cranium. (b) Entrance site (after pre-autopsy removal of the head hair) with a roundish skin hole surrounded by irregular soot deposits. (c) Close-up view of the entrance wound. (d) Circular bone defect in the outer table of the skullcap, approximately corresponding to the diameter of the steel bolt. (e) Internal aspect of the skull showing cone-shaped widening of the bone defect. (f) Close-up view of the inner table. (g) Punched-out bone fragment connected to a patch of hairy skin recovered from the end of the wound channel.

Stud Guns

In this context, powder-actuated fastening tools are only mentioned insofar as it serves to distinguish between stud guns and humane killers. Stud guns are similar to ordinary firearms and use blank cartridges to fire pins, threaded studs, nails, or fasteners into wood, concrete, masonry, or metal structures, so that other materials or objects may be affixed to the receiving part. The blank cartridges range in caliber from 0.22 to 0.38 in and are loaded with fast-burning propellants. The external appearance of a stud gun resembles a large pistol with a flat face plate attached to the muzzle, which has to be pressed firmly against a solid surface before it can be fired. The purpose of this built-in safety mechanism is to prevent free flight or ricochet of the stud. Nevertheless, numerous accidents and a few suicides have occurred with stud guns.

A major cause of injuries and deaths is perforation of flimsy walls with the result that a worker behind or a bystander is struck by the nail. Many accidents are due to ricochet of the steel missile which, as a result, becomes bent. Thus the finding of a bent nail on radiographs of the victim can be helpful in determining the circumstances of the accident. In suicides, the most common sites for a stud gun entrance wound are the chest, the forehead, and the temple.

The morphology of skin wounds from studs is variable, for example, a distance shot with a straight and pointed steel missile causes an inconspicuous slit-like puncture wound, whereas a bent stud after ricochet produces an irregular, jagged laceration with abraded margins. In (suicidal) contact shots, stellate entrance wounds surrounded by muzzle imprint marks have been observed.

Laboratory Analysis

Examination of Firearms

If necessary, some nonfirearms examinations first could be performed in other areas of the crime laboratory or by other private examiners, such as processing the firearm for latent fingerprints. Once these other examinations are completed, the firearms examiner should do a quick safety check, confirming that the firearm is completely unloaded and free from bore obstructions. At the same time, he/she can check for and preserve any trace or biological evidence that might have been missed – hairs, fibers, soils, concrete, glass, blood, and body tissue that could be present on the muzzle or other parts. If none are present, then next is the task of identifying the make and model of the firearm. This can usually be accomplished by observing manufacturer and sometimes proof markings on the frame, receiver, and/or barrel. The examiner usually performs overall-length and barrel-length measurements during this preliminary phase, and checks for any outward evidence of alteration.

Usually the firearm is tested for safe and normal function. Multiple rounds of ammunition are fired, the safety mechanisms/devices are checked for proper function, and any abnormalities are noted in the cycle of fire – which consists of feeding, chambering, locking, firing, obturation, unlocking, extraction, ejection, and cocking. (Obturation is the sealing of gases owing to expansion of the cartridge case or shotshell in the chamber, or owing to the expansion of a bullet's base as it begins to move into and down the barrel. Obturation failure is very uncommon and not necessarily observable, though it could easily result in gases escaping through or around the breech.) If the examiner needs to obtain bullet velocities, he/she can do so by means of a timing device called a *chronograph*, which is specially designed for this purpose.

If test-fired bullets are to be recovered for microscopic comparison purposes, then sometimes the function testing can be performed at the same time the examiner fires into a water tank or other suitable bullet-recovery device. In other cases, however, this procedure would be ill-advised. For example, for semiautomatic firearms, testing the self-loading mechanism for normal function obviously requires that multiple cartridges or shotshells be loaded into the firearm's ammunition holder, the magazine. If the disconnecter device within the firing mechanism fails or has been altered, then the firearm can fire in fully automatic mode (similar to a machine gun), possibly resulting in injury or physical damage if the muzzle of the firearm climbs significantly during recoil. Where this event is considered even a remote possibility, and clearly also for fully automatic firearms, function testing should be conducted on a separate firing range.

If the firearm appears safe and normal but fails to fire or otherwise fails to function normally, then often the examiner will partially disassemble the firearm and search for explanations. If a part is defective, for instance, a replacement part

may possibly be borrowed from a duplicate firearm in the laboratory's collection, or purchased separately. Then the function test can be repeated. In some cases, the examiner has reason to believe a firearm could be unsafe to fire. In these instances, he/she may decide to use a remote-firing device, or fixture, that enables the examiner to actuate the trigger from a safe location.

Measuring the force required to release the trigger mechanism's sear (the force required to 'drop the hammer' by pulling on the trigger) is customarily part of a normal firearm examination and most often performed after test-firing, for the reason that the firearm possibly can be damaged by this testing. The trigger pull can be measured by an electronic force gauge, by a mechanical spring gauge, or by an apparatus designed for the purpose that uses hanging weights of known value. The result can be especially significant in some cases if the measured force is small or well below the manufacturer's tolerances, for clearly, as the sear-release force decreases, a scenario involving a possible unintentional discharge presents itself.

If indeed an examiner receives a firearm in which a possible unintentional discharge is at issue, then further testing can be performed. The usual protocol calls for the firearm to be struck with a mallet (usually rawhide or hard rubber) on all six planes; that is, on the muzzle, butt, bottom of receiver or frame, top of receiver, and on the sides, while the firearm is loaded with a primed cartridge or shotshell. The latter two merely consist of ammunition for which the bullet, slug, or shot has been removed, along with other components in the case of a shotshell, along with removal of the propellant. Only the primer is left intact, and when struck with sufficient force by the weapon's firing pin – whether from an examiner pressing the trigger or from the firearm being struck by the mallet without the trigger being pressed – the result is merely a 'pop.' The usual protocol can be supplemented given the nature of the alleged incident. Most typical is the claim that the firearm was accidentally dropped and it discharged. Thus, in addition to the six-planes testing, the examiner can actually drop the firearm. This should be done in a manner that duplicates the incident as closely as reported and as reasonable, provided the contributor understands that in some instances damage to the firearm can result.

Uncertainties and Limitations

Occasionally serial numbers (if the firearm bears one) are found on internal parts of the firearm, though an examiner must avoid confusing serial numbers with manufacturer's production numbers. Caution also should be exercised inasmuch as it is possible that aftermarket and black-market firearms were assembled from parts. Overall- and barrel-length measurements are usually straightforward and performed according to a protocol; but if a measurement is important for statutory or other reasons and the measured values are

close to the statutory limit, then the measurement uncertainty must be assessed. The accuracy of the measuring instrument should be known, along with how the measurement varies with repeated trials. In some cases the statistical standard deviation should be calculated and interpreted in light of the statutory limit. The same uncertainty considerations can apply to trigger pull measurements, especially in certain cases. The accuracy of the instrument should be known, through either a recent calibration or a performance check with a known reference standard, and the repeated trials recorded and sometimes analyzed for statistical variance.

Of course, function testing also does not reach perfection, and what held true for a firearm's performance in the past may not be reflected in the current testing results. Parts may function normally up to the time of testing, at which time a part or parts may fail. The nature of commercial test ammunition can vary to a small degree, with a light firing pin strike detonating some cartridge or shotshell primers but perhaps not others. If testing is performed outdoors in colder weather, any oils and grease in the firing mechanism will increase in viscosity (thickness), possibly affecting function. These considerations seldom present the examiner with genuine problems, but he/she should always be mindful of the possibilities.

Examination of Fired Ammunition Components

As with the firearm, the examiner should first carefully observe fired bullets and cartridge cases for trace evidence such as clothing fibers, soil or concrete material, glass or wood fragments, paint, and blood or other tissues. If present, they should be preserved for examination by other experts.

Level-One Analysis: Class Characteristic Marks

These characteristics are permanent and measureable features that are part of the firearm's original design and belong to a 'class' of firearms. Many features could, in principle, qualify as class characteristics, but in practice only some are forensically relevant and leave distinct and reliable markings on fired bullets and cartridge cases. These include such features as the number of lands and grooves in the bore of the barrel; their direction of twist (clockwise or counterclockwise, or right or left); and their respective widths. They also include the size and shape of the firing pin tip, the size and shape of the firing pin aperture, and the size and locations of the extractor and ejector. More unusual features can also qualify, such as the chamber flutes designed into some Heckler & Koch firearms, which leave telltale gunshot-residue lines on fired cartridge cases. The caliber, or diameter, of a barrel's bore is also a class characteristic that is obviously of forensic value. The degree of twist, or pitch, of a barrel's rifling is also a class characteristic, but seldom used in recent times. The reasons for this are that the uncertainty of measurement is large, and measurements are impossible with many bullets that have been deformed or mutilated from impact.

The forensically relevant class characteristics are directly observable from the markings imparted to fired bullets and cartridge cases. The rifling characteristics on bullets – commonly

known as general rifling characteristics (GRCs) – are directly measured and counted. Various methods can be used to measure the widths of rifling impressions on bullets, but all involve microscopic examination and a measuring scale of some type (such as an eyepiece reticle), or a measuring device such as a micrometer. On deformed bullets, often the direction of twist can be determined by observing the nature of the land-impression edges. The leading, or driving, edge of a land impression is usually deeper and on the same side as the direction of twist. That is, with the bullet in nose-forward orientation, if the driving edge is on the left side of the land impression, then the direction of twist is also leftward, or counterclockwise (the direction holds regardless of whether one is observing a bore from the breech end or the muzzle end).

The level-one analysis culminates in a comparison of specimens. In the case of complete, intact bullets, for example, this can be a comparison of measurements/counts/directionality, a visual comparison of impression widths under a microscope, or all the above. If the number of land and groove impressions present on the specimens is different, then clearly the bullets were fired from different barrels (a conclusion of elimination, or exclusion). If the calibers or directions of rifling twist are clearly different, or if the measured widths of the impressions are consistently and significantly different, then the same conclusion is rendered. But if the rifling impressions are identical

in number and direction of twist (or with bullet fragments, potentially identical), and their measured widths not significantly different, then a level-two visual examination under the comparison microscope should follow. (The same firearm can fire bullets that yield slightly different impression widths, owing to differences in ammunition, in bullet jacket material, in ambient temperature; or owing to deformation or the presence of bore lubricants, among other possibilities.) Using the comparison microscope, the entire length of the impressions can be compared, their respective edges more closely observed and compared, and a more reliable determination made – without the interference of possible ‘noise’ from measurement uncertainty – for whether the widths are close enough to justify a level-two analysis.

The same procedure is undertaken for fired cartridge cases, though in this instance measurements of class characteristics are seldom performed. Rather a visual, comparison microscopic inspection is undertaken to check for congruence in firing pin impression size and shape, in the size and shape of the firing pin aperture, and in the relative positions of extractor and ejector, among other possibilities. Again, the observation of clearly incompatible class characteristics between two cartridge cases usually eliminates the possibility of their having been fired from the same firearm. (Incompatible marks from extractors and ejectors are less definitive for the reason that they can be imparted to cartridge cases by simply cycling unfired ammunition through a firearm’s mechanism.) If

the observed class characteristics are the same, however, then the analysis proceeds to the second level.

Evidential weight of a class characteristics match

In the simplest of terms, a class characteristics match between an evidence (or ‘questioned’) specimen and a test-fired specimen merely eliminates possibilities. That is, a firearm should not normally be excluded if its class characteristics match those of the submitted evidence, but all other firearms with different class characteristics are excluded. But this information alone gives no quantitative indication as to probative value. Unlike an old serological test (which results might show a blood stain is type A-negative, the defendant’s blood also type A-negative, and with A-negative occurring at a specific frequency in the relevant population), there is no existing database from which an examiner can obtain the prevalence of specific firearm class characteristics within a relevant geographical area. Examiners and firearm experts, in general, are fully aware that many GRC patterns are quite uncommon. And to observe such a GRC match in an actual case is thus highly probative (e.g., perhaps out of all the firearms in existence, only one in 1000 or 10 000 share these GRCs). However, the actual figures are unknown, and thus when a class match is the only examination result, in the judicial sphere examiners tend to be the questioned cartridge case or bullet was fired from the submitted firearm. A verbal scale (i.e., qualitative GRC

likelihood ratios), however, is sometimes provided in countries such as New Zealand.

Uncertainties and limitations

Examiners must avoid overinterpreting class characteristics that display only slight differences, and this comes only from training and experience. Already mentioned are the slightly different land and groove impression widths that can result from varying conditions. This also pertains to observations of firing pin and firing-pin aperture impressions; some variations in size and shape are to be expected when cartridge cases have been fired from the same firearm. The relative positions of extractor and ejector can, in theory, prove problematic if cycling a cartridge multiple times through a firearm mechanism results in the observation of a false 'clockface' orientation between the two types of marks. Normal measurement error must also be considered, and often recorded, when measuring caliber and rifling widths.

Though probably quite rare in occurrence, examiners also must be mindful, for example, that in theory firing pins can be replaced or altered, and that ammunition can be fired in so-called subcaliber devices. For example, a specially designed and loaded 38 special chamber-and-barrel insert could be dropped into a break-open 12-gauge shotgun and fired. The GRCs on the bullet would match those of the subcaliber device's barrel, not those of the shotgun, especially given that the shotgun has a larger bore and very likely is unrifled.

Level-Two Analysis: The Microscopic Comparison

If the level-one analysis of class characteristics fails to eliminate specimens as having originated from the same firearm, then the examiner moves the specimens to the comparison microscope. This instrument comprises two microscopes connected by an optical bridge. Thus, it allows for two objects to be observed and compared side by side. When an examiner observes two fired cartridge cases or two fired bullets in this manner, and if the microscopic detail – whether comprising striated scratch marks or impressed marks – reaches a sufficient level of correspondence, then a definitive match conclusion is usually warranted.

At its core, the method for decision making in this procedure is no different in principle than for other types of comparative analysis such as those used in, for example, radiology and field geology. In training the radiologist observes images from x-rays, magnetic resonance imaging scans, positron emission tomography scans, computerized axial tomography scans, sonograms, and so on, and in conjunction with a wealth of background medical knowledge must learn visually to distinguish normal tissue from abnormal tissue, normal structures from abnormal structures; the field geologist learns to visually distinguish between, say, feldspar from nonfeldspar minerals. Similarly, during his or her training, the firearms examiner observes many known-match specimens and many known-nonmatch specimens. Doing so, she learns how much microscopic correspondence occurs in one class of specimens versus the other, and thus learns to reliably effect identification conclusions in actual casework and in proficiency and other types of validity testing. Clearly, the exact criteria used are observer dependent; that is, the decision making is subjective. The

criterion is laid out formally in the AFTE (Association of Firearm and Tool Mark Examiners) Criteria for Identification Committee report in the July 1992 issue of the *AFTE Journal*. Therein the report provides that definitive matches can be affected when the surface contours of two toolmarks are in 'sufficient agreement.' And sufficient (or significant) agreement occurs

... when it exceeds the best agreement demonstrated between toolmarks known to have been produced by different tools [such as firearm barrels or breechfaces] and is consistent with the agreement demonstrated by toolmarks known to have been produced by the same tool ... (AFTE, 1992)

The validity of this comparison procedure rests on the empirical reality that microscopic marks imparted to specimens fired from firearm 'A' are usually highly similar; those from firearm 'B' are highly similar; but that the microscopic marks are significantly dissimilar when comparing 'A' specimens to 'B' specimens. Research indicates that this observation virtually always holds, except for instances in which a manufacturing process for a particular part produces so-called subclass marks. These are highly similar microscopic marks that persist on sequentially manufactured items; from, say, breechface #1 to breechface #2 to breechface #3, and so forth, though usually for a fairly short run of items. In theory, these marks can be transferred to fired cartridge cases and bullets and conceivably result in forensic errors, though in various ways competent examiners guard against this possibility.

Sources of error

If a misidentification is classified as a Type-1 error, and a miselimination as a Type-2 error, then source categories can be enumerated for them. They are as follows:

1. A random, coincidental match. That is, of all the bullet and cartridge-case specimens potentially in existence, a few might look highly similar out of sheer coincidence; similar enough to fool an examiner. Pertains to Type-1 errors only.
2. A misidentification owing to the existence of subclass marks that have been transferred to bullets or cartridge cases. Pertains to Type-1 errors only.
3. An examiner's use of an inappropriate identification or elimination standard. This is usually the result of inadequate training, or of incompetence.
4. Laboratory or quality assurance errors. These can stem from the mislabeling of specimens, confusing test with evidence specimens, erroneously transferring information from examination notes to a report, faulty microscope optics, rushed examinations, and so on.

From the results of various types of validity testing, the results of proficiency testing, and for various technical and probabilistic reasons, by all indications categories #3 and #4 are responsible for the vast majority of Type-1 and Type-2 errors in firearms analysis. These types of errors in testing have been infrequent, especially in tightly controlled validity tests, and there's no evidence these errors occur but very infrequently in actual casework. But the chance of a Type-1 or Type-2 error is not zero, and thus over the years, examiners have moderated the strength of their identification and
